The fuel mixture is divided into a large number of narrow jets by means of deflecting strips of copper, suitably machined, in the burner boxes. The usual long pulverised fuel flame is thus replaced by a large number of short jets; each burner has a special long water-cooled projection, top and bottom, which are joined together at each end.

In addition to the main burners, there is an auxiliary burner at the back of the ashpan.

The pulverised fuel is kept in a cylindrical container on the tender, in the bottom of which two main and one smaller auxiliary fuel feeding screws are placed, one on each side. All these screws are driven by a small engine by means of a pinion engaging with a lay shaft, which in turn engages by means of gear wheels with the main screw driving shaft. These gear wheels can be engaged with the screw shaft by means of friction clutches. Each main feeding screw can be operated independently.

The fuel supply is regulated by altering the speed of the engine. The auxiliary feeding screw can also be operated independently.

The primary air, which is approximately 40 per cent. of the air required for combustion, is supplied by a turbo fan, and is forced through down pipes into the two mixing chambers placed at the delivery end of the feeding screws. The fuel and air are here mixed together intimately and then led to the burners, through pipes with flexible ball and socket connections between engine and tender.

The secondary air for complete combustion is obtained as usual by means of the suction caused by the blast-pipe exhaust. This air enters the ashpan through the front damper door, passes up an air passage formed between the front wall of the brickwork and the ashpan, leading up to an opening between the wall and the brick arch, and enters the firebox immediately under the brick arch.

The auxiliary screw also feeds the fuel into a mixing chamber.

The air for the auxiliary burner is provided by a small fan geared to the flywheel of the steam engine. The fuel and air mixture is driven through a hose-pipe connection to the auxiliary burner, which is placed beneath the foundation ring at the back end of the ashpan. The auxiliary burner is used for heating up, or when standing in a station, running down grades, etc.

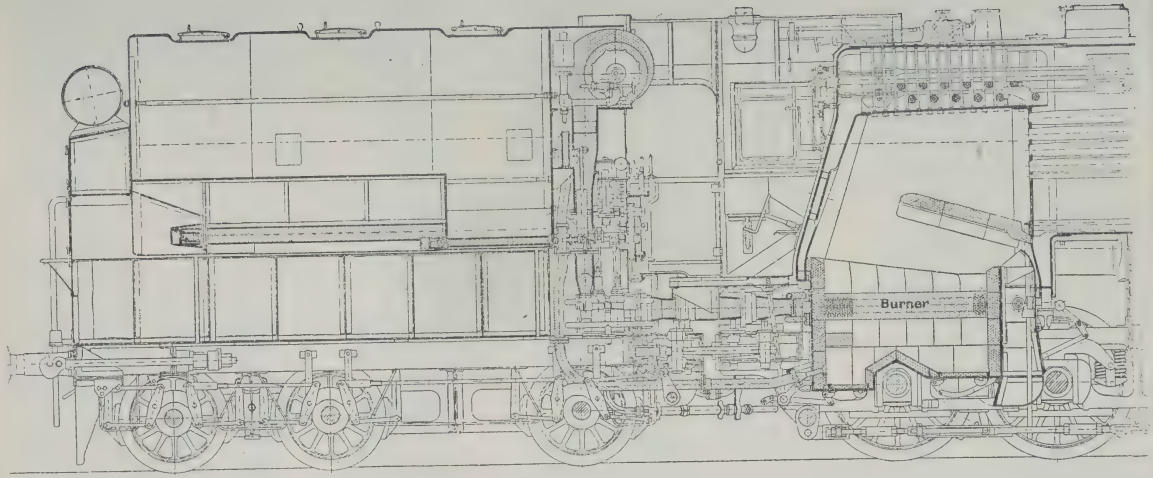

FIG. 25.—Arrangement of 'A.E.G.' Pulverised Coal Fired Locomotive showing lateral louvred Burners in Combustion Chamber or Fire-box, Main Screw Feeders, and Pilot Feeder and Burner.

The steam also drives a pump for the cooling water, which circulates through both burners and thus passes to a feed well, where it is used as feed water.

With the A.E.G. pulverised fuel system, fuel of low quality can be easily used. The efficiency of the boiler is increased, due to a much smaller quantity of air being required for complete combustion, thereby causing a considerable saving in fuel. The evaporative capacity of the boiler is not dependent on the strength or skill of the fireman.

A special advantage is that the steam requirements of the locomotive can immediately be suited, and that, further, the combustion is smokeless and sparkless.

The system is remarkable for its low fuel consumption and its high evaporative capacity over a long period. A fuel consumption of 1·24 kg./per h.p. hour with a fuel of 5,400 W.E/Kg. calorific value has been attained.

Another pulverised fuel system in use on German railways is that developed on behalf of a number of leading German firms by Messrs. Henschel and Sohn. The main points of difference with the A.E.G. system lie in the position and construction of the burners. These are fixed below the back plate of the fire-box and discharge the fuel towards the front. The end of each burner has a large square opening covered by a plate perforated with a considerable number of holes which form individual jets. No water-cooling of the burners is necessary, and the whole of the air of combustion is supplied through the burners.

See also Section XXXIV.

Coal Consumption.

The average rate of combustion in British express engines on heavy service is about 100 lbs. per sq. ft. of grate area per hour, and about 50 lbs. of coal per mile; the maximum rate may reach 160 lbs. per sq. ft. of grate area per hour.

According to the Railway Returns for 1925, the lbs. of coal consumed per engine-mile for the four British railway groups were: for passenger service, 40·00 to 53·11 lbs., for freight service, 54·82 to 70·06 lbs.

The evaporative power of locomotive boilers amounts to from 7 to 10 lbs. of water per pound of coal consumed. Longridge states that no rule can be fixed as to the best relative proportions of heating surface between grate area, fire-box, and tubes. It is an axiom that the capacity of a locomotive depends entirely upon its fire-box.

The consumption of fuel in a locomotive engine at rest, as when standing in a station or at a signal, is about one-fifth of that consumed when the engine is in motion. When standing at a shed with fire banked the consumption is very much less.

In a modern engine about 3½ cwt. of coal is actually consumed in raising steam in a boiler from cold water, and about 2½ cwt. from hot water. Some 10 cwt. is required for making up the fire before working a heavy train.

Water Consumption.

With a piston speed of 900 ft. per minute and a boiler pressure of 175 lbs. per sq. in., locomotives using saturated steam require about 24 lbs. per i.h.p. hour. The evaporation is approximately 8 lbs. of water per pound of coal, or 9½ lbs. from and at 212°F. The coal consumption is therefore 3 lbs. per i.h.p. hour. Locomotives using superheated steam require 25 per cent. less, or about 18 lbs. of steam per i.h.p. hour. The coal per i.h.p. is 12½ per cent. less, or roughly 2½ lbs. per i.h.p. hour, the evaporation being 7 lbs. of water per pound of coal.

Lubricating Oil Consumption.

The oil consumption of different railways varies considerably, but under favourable conditions 1 lb. of cylinder oil and 4 lbs. of engine oil are required per 100 miles. Superheater engines use rather more cylinder oil than non-superheater, and the quality of the oil is more expensive.

The oil consumption of the 4-6-0 Great Western engines averages 5 lbs. per 100 miles.

According to the Railway Returns for 1927, the consumption of lubricating oil per running-mile for the four British railway groups was: for passenger service, 6·40 to 7·26 pints; for freight service, 6·77 to 8·20 pints; for shunting service, 4·60 to 6·29 pints; for all services, 6·54 to 7·19 pints.

Sight feed lubricators on the hydrostatic principle, delivering oil to the steam pipes, are used on both superheater and non-superheater engines. It is more usual on superheater engines to employ a mechanical force feed lubricator driven by an attachment to some part of the engine motion. In this case oil is delivered direct to the piston valve heads and the middle of each cylinder bore.

The practice of feeding oil to the crowns of axle boxes by mechanical lubricators is also extending, more particularly in the case of heavy eight wheels coupled mineral engines.

For LUBRICATION AND LUBRICATORS, see p. 977.

Tenders.

The water capacity of tenders on British railways varies considerably. On the L.M. & S. Railway many tenders are under 3,000 galls., and the Great Western Railway uses 3,500 galls. for the largest engines, but these railways possess numerous water troughs, so that light six-wheeled tenders suffice. Large bogie tenders of some 5,000 galls. capacity are in use on the Southern Railway and on the Caledonian section of the L.M. & S. Railway.

The coal capacity does not vary so much, and lies between five and seven tons, depending on the size of the engine.

The connection between engine and tender consists of a simple eye-ended bar with one or both holes elongated to allow for the buffing which is taken up at the centre on a massive helical spring through which the bar passes. Safety links or loops are provided on either side, but only come into operation in the event of the bar breaking.

Several railways prefer side buffers as they help to damp out oscillations of the engine by the friction of the rubbing surface. The central arrangement is better for sharp curves.

In order that long non-stop runs may be made on the L. & N.E.R., some tenders have gangways through them which communicate with the train, and so enable a change of enginemen to be made on the journey.

Water Troughs.

Effective length is from 440 to 560 yards. Theoretically a quantity of about 1,000 gallons can be picked up, the mouth of the scoop being at rail level and $1\frac{1}{2}$ ins. below water level. In practice considerably more is obtained owing to the heaping up of the water in front of scoop, the maximum being obtained at 45 miles per hour with some 1,700 galls. At higher speeds there is a considerable loss by spray. The lowest speed at which water can be picked up is 15 miles per hour.

When running at 60 miles an hour over a water trough $\frac{1}{4}$ mile long, a locomotive tender will pick up about 1,000 gallons or 10,000 lbs. of water.

Examination of Locomotives at Running Sheds.

A failure on the road is a serious matter, and the best way of reducing breakdowns to a minimum is by periodical examinations. The following is a list of the usual examinations of the L. & N.E.R. (G.N. Section):—

Slide valves:—	
Piston valves	2 months
Richardson's	2 „
'D' valves, $\frac{7}{8}$ in. thickness	4 „
'D' „ $\frac{3}{4}$ and $1\frac{1}{16}$ in. „	3 „
'D' „ $\frac{5}{8}$ and $\frac{9}{16}$ ins. „	2 „
'D' „ $\frac{1}{2}$	1 month
Pistons	3 months
Tender tanks	1 month
Drip valves	1 „
Safety valves	6 weeks
Ball valves in water gauge frames (dependent upon quality of water in district)	2 months
Lead plugs	1 month
Large ends	3 months
Small ends	6 months
Vacuum regulating valves	1 month
Water scoops	1 „
Fire-boxes	1 week
Axle-box pads	3 months
Injectors	1 month
Main steam pipes on superheated engines	1 „
Tender wheels gauged	1 „
Leading wheels of 2–4–0 type gauged	1 „
Engine and tender tyres gauged	1 „
Mechanical lubricators to slide valves and pistons	2 months
Mechanical lubricators to axle-boxes	1 month

Cracked frames, flaws in connecting and coupling rods, or any part of motion, loose tyres, etc., should also be watched for. (*G. A. Musgrave*, '*Proceedings*, *Inst. Loco. Engrs.*')

Engine and Tender Tools and Equipment.

CARRIED IN TOOL BOXES.

Flat chisel.
Pin punches (large and small).
Chipping hammer.
Wrench for union nuts.
Complete set of spanners.
Adjustable wrench.
Tommy bar.
Large can for engine oil (6 to 8 quarts).
Large can for cylinder oil (6 to 8 quarts).
Small can for paraffin (about 1 quart).
Spring valve oil feeder, long spout.
Spring valve oil feeder, short spout.
Flare lamp.
Case of fog signals.
Red flag.
Hand sweeping brush.
Packing drawer } (if required).
Tallow pot }
Spare glasses for water gauge.
Spare glasses for sight feed lubricator (if fitted).
Spare packing rings for glasses.
Copper wire for trimmings.
Worsted for trimmings.
Spare cotter pins.
Spare nuts.

CARRIED ON TENDER.

Fire rake
Pricker
Dart
Tube scraper
Clinker shovel
} (length to suit firebox).
Slice (to suit depth of firebox at back).
Coal hammer.
Coal pick.
Pinch bar.
Bucket.
Fireman's shovel.
Screw-lifting and traversing jack (if specified).

OTHER EQUIPMENT.

Full set of head and tail lamps.
Full set of head boards or discs (when used).
Water gauge lamp.
Sight feed lubricator lamp (if required).

SPECIAL EQUIPMENT AT SHED FOR CLASS OF ENGINE.

Spanner for brake screw adjusting nuts.
Box spanner for fusible plugs.
Ashpan rake.

Brakes.

In addition to hand brakes the majority of engines and tenders are fitted with power brakes, usually the standard Westinghouse or Automatic Vacuum apparatus (page 640). Some of the large railways manufacture their own vacuum brake fittings. Goods engines not fitted with a continuous brake have a simple steam brake. Many engines are fitted with a steam brake working automatically with the vacuum by means of a valve of simple construction which can either be controlled by the vacuum in the train pipe or by hand. This is found to be a convenience, and the brake cylinders being of small diameter occupy but little space under the engine. The arrangement is extensively used and gives very satisfactory results.

Instead of a small ejector for maintaining the vacuum in the train pipe, several railways employ a vacuum pump about 5 ins. bore directly driven from one of the crossheads of the engine. As the pump is capable of creating a high vacuum, a relief valve is provided to limit the vacuity. On the Great Western Railway this is set for 25 ins., resulting in a running vacuum of 26 ins. of mercury. Other railways set the valve for the standard 20-inch vacuum, which results in 22 inches being maintained when running. Less trouble from pumps running hot is experienced with the higher vacuum, and the size of brake cylinders or leverage is reduced a little on account of the greater available atmospheric pressure, but no practical difficulties arise in the interchange of rolling stock with other railways.

Under average conditions as to load, leakage, and number of stops, the steam required by a vacuum ejector in maintaining a 20-in. vacuum results in the consumption of 42½ lbs. of coal per hour. The power absorbed by a vacuum pump coupled to the cross-head of the engine is equivalent to a consumption of 15 lbs. of coal per hour with a 20-in. vacuum, and 17½ lbs. per hour with a 25-in. vacuum.

(*J. N. Gresham, 'Journal of Inst. of Loco. Engineers.'*)

The percentage of brake power—that is, pressure on brake blocks in relation to load on wheels—should not exceed 75 per cent. for coupled wheels and 100 per cent. of weight when empty for tenders. If bogie wheels of engine are braked the percentage should not exceed 50 in order to minimise any chance of skidding.

To avoid frequent taking up of blocks brake leverage should not be too great. With steam the air brakes leverage is about 7 to 1; vacuum brakes are sometimes as much as 14 to 1 on account of difficulty of finding room for large cylinders. With this ratio a 7-inch piston travel allows ¼ inch clearance for blocks and ¼ inch wear.

Steam Rail Motor Cars.

A large number of rail motor cars were built between the years 1904 and 1909. The Great Western Railway still have many of these cars, some of which are 70 feet long over headstocks. The cylinders are 12 ins. by 16 ins., the wheels 4 ft. diameter, water capacity of tanks 450 galls. The boiler is vertical, 4 ft. 6 ins. diameter with cone top, and has 458 tubes 1⅛ in. diameter, total heating surface 659 sq. ft. and grate area 11½ sq. ft. The pressure is 160 lbs. per sq. in. and the tractive effort 6,912 lbs. The 70 ft. cars seat 61 passengers and the weight on motor bogie is 26·9 tons, and on the trailing bogie 16·25 tons. Walschaert valve gear is fitted.

The practice on the L.M.S.R. and S.R. is to use up obsolete locomotives and carriages by suitably converting them for motor services. A small tank engine is attached to one or more trailer cars to form a unit which can be driven from either end. When pushing the car, the locomotive is controlled by the driver from the opposite end of the train by means of levers and rods with universal joints connected to the regulator. A brake valve and whistle cord are provided and an electric bell signal enables the driver to communicate with the fireman on the footplate. In some cases control of the regulator is by means of compressed air or vacuum.

A recent development is the 'Sentinel-Cammel' design of car. This is of very light construction, and approximates more to tramway practice. The 'Sentinel' type of steam road wagon boiler and engine supplies the motive power. In one instance the coal consumption (inclusive of lighting up) is given as 6·27 lbs. of Welsh coal per mile, the water consumption 3·89 gallons per mile, and the total cost (inclusive of fuel, wages, repairs, depreciation, etc.) as 6·16 pence per mile. A similar type of car is the 'Clayton.' Both types are in use on branch lines of the L. & N.E.R., and numbers are at work on Colonial railways.

The 'Sentinel' and 'Clayton' power units have also been applied to small locomotives for light work on branch lines or for shunting purposes.

ROLLING STOCK.

(Revised by H. Holcroft, M.I.Loco.E.)

Recent Developments in Carriage and Wagon Stock

No very radical departures have been made in carriage and wagon stock on British railways, but in the United States steel is being use to a large extent for passenger and freight car bodies. On British railways galvanised steel plates of about $\frac{1}{16}$ in. thickness are now being used for panels of carriages, but anything approaching an all-steel construction for bodies is very much heavier than with wood. On account of the doors with the compartment system, it is not possible to make use of the side of the body as a girder, as in the open American cars with end doors. The L.M.S. Railway have put into service a number of steel coaches of the open type with central gangway and end doors. The under-frame, roof, and sides form a box girder, and no truss rods are needed.

The L. & N.E.R. and Southern Railway use the American type of automatic coupling and vestibule for some of their main-line trains. In order that these vehicles can be attached to ordinary stock, the coupler is hinged and can be dropped down, exposing a hook for screw coupling. Side buffers are provided, and these have a loose sleeve which can be removed to allow the buffers to be pushed back when the automatic coupling and vestibule with central buffers are in use.

Pullman cars of the American type are extensively used on the Southern Railway, and to a lesser extent on the L. & N.E.R., L.M. & S., and Metropolitan Railways. Mr. Gresley's twin coaches, as used on the L. & N.E.R., consist of a pair of bodies hinged together The outer ends rest on bogies in the usual way, but there is only one bogie for the inner ends, the bogie pin being at the hinge between the coaches. A flexible gangway connects the two bodies. This system has been extended to complete trains, so that a set train of five coaches has only six bogies.

The G.W.R. has also built some trains of articulated coaches.

The high-capacity bogie wagon makes but slow progress on British railways, owing to the lack of terminal facilities. The tendency is to build 4-wheel wagons of 12, 15, or 20 tons capacity. The fitting of a continuous brake to goods trains is limited to special trains for perishables, ballast, etc. Its more general application is retarded by the presence of a large number of private owners' wagons and the high capital costs involved.

The container system of transporting goods has been introduced on British railways. Large boxes fitted with doors are filled at the factories, transported by road and then placed on railway wagons by a crane.

Another new type of wagon is that for carrying milk. This consists of a large cylindrical tank, glass lined.

General utility vans have been introduced by the Southern Railway. These are 4-wheeled vehicles, with a wheel base of 21 ft., and they have end as well as side doors. By means of special fittings they are adaptable for a number of purposes besides passengers' luggage, such as milk cans, motor-cars, road vehicles, fruit baskets, theatrical scenery, aeroplane parts, etc.

Axle Boxes.

These are usually of cast iron: for carriages oil boxes are universal, and a large number of new wagons are now being fitted with them instead of grease boxes. An oil reservoir in the bottom of the box conveys oil by capillary attraction, either by cotton-waste packing or by means of a worsted pad with tail trimmings supported on springs. The bearing or 'brass' is of gun-metal, or gun-metal lined with white metal. Some white metals have a tin base and contain about 60 per cent. tin and 25 per cent. of lead, with 10 per cent. antimony and a little copper. The lead base alloys have about 76 per cent. of lead, 15 per cent. of antimony, 6 per cent. tin, and a small percentage of copper.

The oil used is a mineral oil, and sometimes contains a trace of fatty oil.

A leather-faced dust shield prevents dirt or water creeping in at the back of the box.

Roller Bearings.

Experiments made on British railways seem to indicate that the friction of a plain bearing lubricated by an underpad is even less while running than a roller bearing, although the starting effort required with the latter is reduced, as also the oil consumption.

Owing to the higher capital cost there is, however, little or no inducement to adopt the roller bearing on British railways. On railways abroad, where the workmanship, maintenance, and materials are not so high-class, so that friction is greater, some advantage is gained by the adoption of roller bearings, and a small saving in fuel is found, sufficient with the other advantages realised to justify the adoption, this tendency being more marked in the Northern countries in Europe having cold winters. The bearings are also applied to trains de luxe in France and elsewhere on the Continent, such as the 'Blue Train' and the 'Golden Arrow.' Favourable conditions for the use of roller bearings are also found in North America, where some of the steel passenger coaches weigh as much as 70 to 80 tons each. Owing to the axle loading the journals are of large diameter, while the wheels are smaller than in England, so that the frictional resistance is high, and the risk of heating increased. The use of roller bearings reduces the friction, enables an easier and smoother start to be made, and obviates the risk of hot bearings, besides reducing oil consumption.

Wheels.

For carriages the wheel with wooden centre, once universal, has now been superseded to a large extent by a steel disc centre of slightly dished form, on which is shrunk a steel tyre having a lip on outside, and secured by retaining ring inside. Tyres are 5 ins. wide and are coned 1 in 20. In order to ensure smooth running, all carriage wheels are carefully balanced. Each pair of wheels is placed on a machine, the journals resting in bearings mounted on springs. When the wheels are revolved at high speed any irregularity in the running can be detected, and a correction made by fastening small plates to the inside of the wheel, near circumference, so that smooth running results.

Wood centres must be bonded by a copper strip between tyre and hub, so as to conduct electric current from rail to rail for operating signalling appliances. Tyre shrinkages are $\frac{3}{16}$ in. for wood centres, and about $\frac{5}{64}$ in. for steel centres.

Wagon wheels are made in a variety of ways. The bossed spoke wheel consists of spokes made from flat bar bent into triangular shape. These are placed together in a mould and a cast-iron boss is cast round them. The outer ends are then welded together to form a solid rim. Instead of casting a boss, it may be forged by placing two discs brought to welding heat on either side of the spokes, and forcing them together in a powerful press. Spoked wheels have also been made by forging spoke bars and building up a wheel. But this has been largely superseded by a cast-steel spoke wheel. A few wheels are being made with steel disc centres, and there are a few solid cast-iron wheels with chilled treads running on British railways. These are on wagons originally built for war service in France.

Journals of axles are sometimes case-hardened, but very good results can be obtained by the simple process of burnishing in the lathe. After the journal is machined, a tool having a small roller at the end is fixed in the slide rest and the journal is rolled all over with considerable pressure; this closes all the pores and leaves a hard, bright surface.

The maximum bearing pressure for journals varies from 500 to 700 lbs. per sq. in. of projected area.

A reduction in diameter by $\frac{1}{4}$ in. is allowed before axles are scrapped.

Springs.

Laminated bearing springs are usually $3\frac{1}{2}$ ins. wide for carriages, and 4 ins. for wagons, with plates $\frac{3}{8}$ to $\frac{1}{2}$ in. thick, approximately.

If L = distance in inches between centres of bearings measured along top plate; b = breadth of plates in inches; t = thickness of plates in sixteenths of an inch; n = number of plates; W = safe load in tons; D = deflection in sixteenths of an inch per ton of load,

$$n = \frac{15LW}{bt^3}; \quad W = \frac{bt^2n}{15L}; \quad D = \frac{2L^3}{bt^3n}.$$

If there are different thicknesses of plates in one spring, it is necessary to find the equivalent number of plates of uniform thickness from the square (or cubes in the case of deflection) of the thickness, thus :—

$$n = \frac{n_1 t_1^2 + n_2 t_2^2}{t_1^2}.$$

See also p. 613.

Buffer springs are largely made of rubber, and are ormed of rubber discs 2½ to 3 ins. thick placed between 6 or 8 metal discs.

For *Helical Springs* see p. 614.

Couplings.

Draw bars should be 1¾ ins. diameter ; they should be made from wrought iron, Grade A, or welding steel. Area of end of eye = area of two sides × 1·2.

Couplings should be made of wrought iron, Grade A, or welding steel. Standard diameter = 1½ in.

Screw coupiings are of wrought iron, or sometimes of steel (B.S.S. 9B).

Draw hooks should be of wrought iron, Grade A, or welding steel. If stamped out, the grain of the iron should be kept running with the hook, an important point sometimes overlooked in second-rate work.

FOR BRITISH STANDARD SPECIFICATIONS FOR MATERIALS USED IN THE CONSTRUCTION OF RAILWAY ROLLING STOCK, see pp. 611 to 620.

LIGHTING AND HEATING RAILWAY CARRIAGES.

STONE'S SYSTEM OF ELECTRIC LIGHTING FOR RAILWAY CARRIAGES.

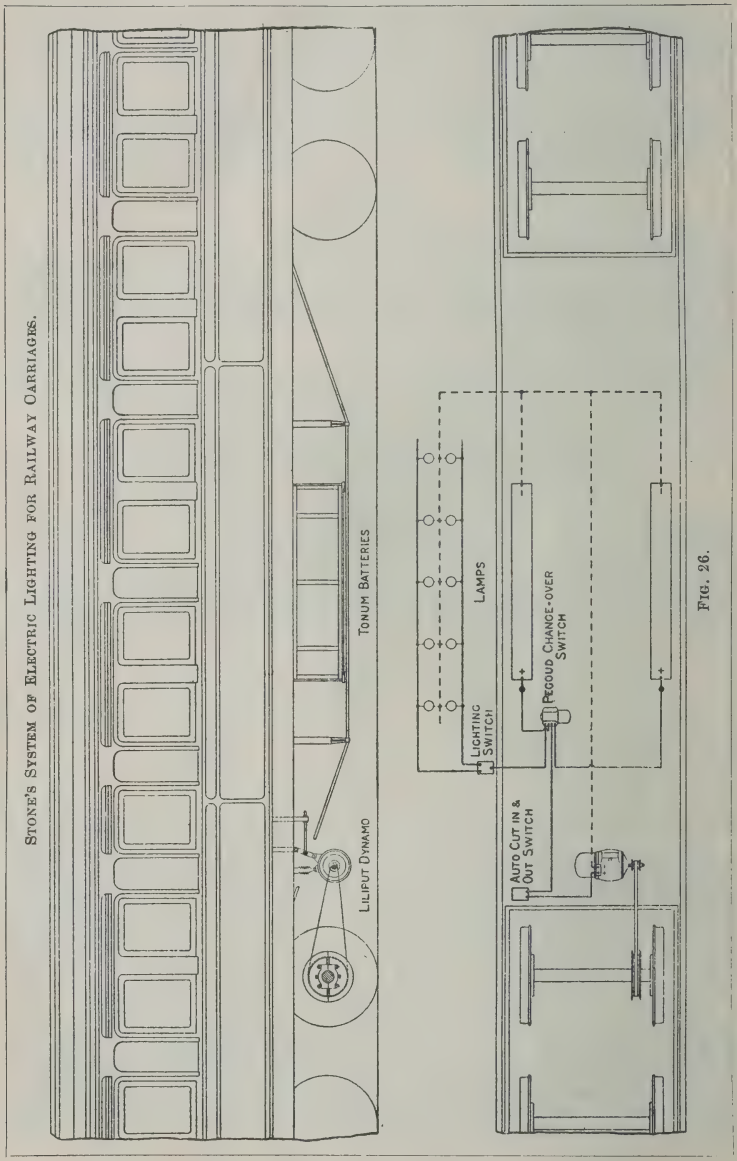
In this system, fig. 26, the dynamo for producing the electric current is suspended from the under-frame of the carriage so that its pulley is at approximately the same level as the pulley on the axle, from which it is driven direct by means of a belt.

Speed of Pulley on Axle of Motor (representing Axle of Railway Carriage).	Equivalent Speed of Train in Miles per Hour (approximate).	Speed of Dynamo, Revolutions per Minute.	Equivalent Speed of Dynamo if no Slip were to take place.	Output of Dynamo. Amperes.
Revs. per Minute 100	12	500	500	0
150	18	750	750	6
175	21	870	875	16
195	23	900	975	18½
225	27	915	1,125	20
275	33	915	1,375	20
325	39	915	1,625	20
375	45	915	1,875	20
450	54	915	2,250	20
600	72	915	3,000	20

However the speed of the train may vary, after a certain predetermined limit has been reached, *the dynamo always runs at a uniform speed and consequently always produces practically the same amount of electricity.* This result is obtained by suspending the dynamo by one corner of its frame by means of an adjustable link, so that the driving belt draws the dynamo out of the diagonal position in which it would naturally hang, thus putting a definite tension on the belt just sufficient to absorb power equivalent to the amount of electricity required. When the pull on the belt (owing to increase in speed of the train) exceeds the weight on the belt, due to the one-sided suspension of the dynamo, the latter is automatically drawn towards the driving pulley on the axle, thus allowing the belt to slip while the armature continues to revolve at its normal speed. That the arrangement is an effectual one is shown by the above table.

The latest developments in the system include the introduction of the firm's 'Liliput' dynamo compactly built on modern lines and provided with ball bearings throughout, a special feature being that all the parts are very easily accessible for inspection or removal. The armature is of the drum wound type with former wound coils, the machine itself being shunt wound.

The centrifugally operated switchgear embodied in the older dynamos is omitted from the 'Liliput' machine, the switching being now effected by a separate automatic cut-in and cut-out switch operating on voltage ; and in the case of a double battery system, a 'Pegoud' battery change-over switch is included, so as to change over the position of the charging and regulating batteries every time the dynamo switches into circuit.



Stone's System of Electric Lighting for Railway Carriages.
Lilfut Dynamo
Tonum Batteries
Lighting Switch
Lamps
Pegoud Change-over Switch
Auto Cut in & Out Switch

Fig. 26.

The 'Liliput' dynamo (in which is embodied the pole-charging device) is made in two forms, either to run at a constant speed, as described above—the output being controlled by means of a slipping belt—or at a variable speed, that is, the speed of the dynamo following the speed of the train, the output remaining constant at all speeds, and as the lamps are switched 'on' or 'off' so the dynamo output increases or decreases according to the demand.

The accumulator being always in connection with the lamps causes the light to be absolutely steady, acting as a regulator to absorb any excess of current generated by the dynamo.

The working parts of the dynamo are enclosed in a movable but dust-proof casing.

A switch is provided to each carriage, so that the lights can be either fully on or entirely off, or where there are tunnels, and the light is required in the daytime, half the lights may be used. When the lamps are not alight, the current is being stored in the accumulator.

'Tonum' batteries are used with either special formation pasted or Plante positive plates. When a single battery is installed, individual cells have twice as many positive plates and are twice as heavy as the cells in the equivalent double battery; and as the latter, *i.e.*, the double battery system, gives the best regulation and is more reliable in working it is always recommended. One battery being directly connected to the lamps keeps the light absolutely steady while the other battery is being charged by excess current generated by the dynamo over and above that required for the lamps, which are supplied by the dynamo through the lamp resistance. On the train stopping, both batteries supply the lamps.

The 'Tonum' type of cell is designed to withstand the rough handling to which cells are unavoidably subjected in railway work, and embodies several valuable features.

The grids of the plates are of such design as to combine efficiency with mechanical strength. The sections are contained in a lead-lined wood box fitted with a lid which does not require any metal holding down bolts or fasteners, and the top of the box is specially formed and the lining so fitted as to prevent any acid from running down between the lining and the wood and gradually attacking the box.

The positive and negative plates are separately supported on the bottom block, eliminating leakage from plate to plate through lodgment of sediment on the surface of the supporting strips. Ample space is provided beneath the plates for any possible accumulation of sediment, and above the plates to allow of a generous supply of acid, so that the cells do not require frequent 'topping' to make good evaporation.

A float is fitted which indicates the level of the electrolyte in the cell, showing at a glance—without opening the lid of the cell—whether the cell requires water.

The electrical qualities of the cell are (1) retention of capacity throughout its useful life and (2) the maintenance of a high initial voltage for a considerable time after the commencement of the discharge.

The whole of the apparatus is of British manufacture and made in London, the system being largely adopted by the leading railway companies throughout the world.

Heating Railway Carriages by Steam.

Heating of trains is by steam from the locomotive boiler. The train piping consists of 1½ in. bore iron piping, and flexible rubber hose connections with universal couplings are provided between carriages. Automatic ball valves and thermostats are fitted for drainage of water. A pressure of 60 lbs. per square inch is the maximum, but 30 lbs. is quite an average pressure for ordinary working.

Several systems are in use, but they may be classed under two headings, high-pressure and atmospheric. In the high-pressure systems, long cylindrical heaters, 4 ins. to 5 ins. diameter, are placed under one seat of a compartment. These are in direct communication with the train pipe, and steam under pressure fills them. As condensation takes place the water is drained away through a thermostatic valve. There are several modifications of this system.

In the atmospheric systems the heaters have an open outlet at one end, and a jet of steam entering at the opposite end expands to atmospheric pressure and condenses on the walls of the heater, the water draining away at the outlet. In some systems regulation of steam is by means of a thermostat, which automatically controls the steam. In others a choke plug in the branch pipe to the heater restricts the supply of steam to the necessary amount.

With coal of such a quality that it produces 7½ times its own weight of steam in the locomotive boiler, the average consumption of coal for the three coldest months should not exceed about 6½ lbs. per axle per hour.

Westinghouse System.

In the Westinghouse system of heating, steam at atmospheric pressure only is used in the heaters, and the temperature of the heaters is thus maintained equal throughout the train.

Figs. 27, 28 show a typical Westinghouse heater. It consists of a tube A with external gills, which provides a large heating surface in comparatively small space, the heating surface being approximately 2¾ times that of a plain tube of the same external diameter.

The gilled tube A, constructed of steel tube with steel gills, is provided with covers B and J. Steam from the branch pipe enters the heater by the inlet D on the lower side of cover J. Tube E is made of a special alloy having a high ratio of expansion, and is attached at one end to socket F. At the other end of tube E is carried valve K, for which the edge of the steam inlet forms a seat at

L. On socket F is formed a projection C. Attached to the cover B, by two studs G and H, is a plate M. The projection C is kept in contact with plate M by spring N (which also serves to press the gland O against packing P). By adjustment of nuts Q, R, S, T, plate M is fixed so that one end

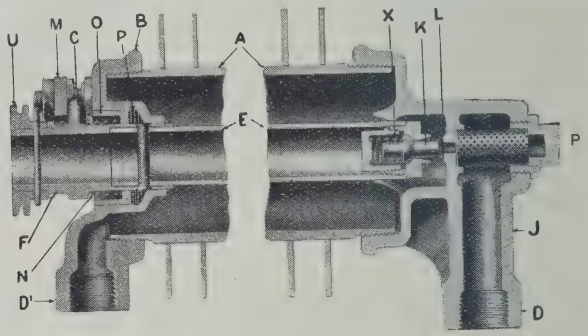


FIG. 27.

of it (*i.e.*, the left-hand end) is slightly further from the heater cover than the other end. In consequence, when socket F is rotated, the projection C slides along the plate M and expansion

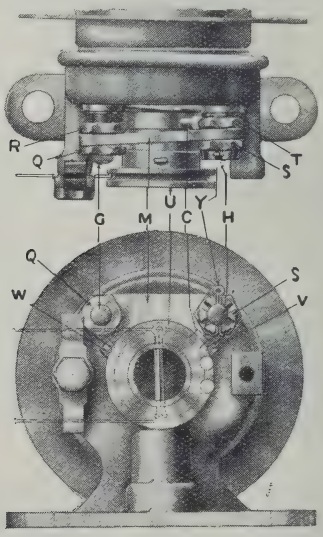

FIG. 28.

tube E moves further in or out of the heater, as the case may be, causing valve K to approach or recede from seat L. The total movement of tube E can be varied to suit requirements by adjusting the inclination of plate M.

Socket F is rotated through a pulley mounted on its outside end by means of Bowden wire, as shown in figs. 27, 28 ; or a crank for rod operation can be fitted if desired.

When the heater is in the ' On ' position, i.e., with projection O rotated to the left-hand side, tube E is drawn back and unseats valve K, allowing a free passage of steam which enters and completely fills the heater, thus rapidly heating up tube A and other parts ; the air and water of condensation escape from outlet D^1, from which a short piece of pipe is led through the floor of the carriage to the outside. As the heater becomes hot, so does tube E, which expands more than tube A for the same rise of temperature. This causes valve K to approach seat L and, when tube E reaches a predetermined temperature, valve K closes the steam inlet and prevents further ingress of steam until the heater cools slightly, when tube E contracts and again allows valve K to open and admit a further quantity of steam. The temperature of the heater is thus maintained practically constant.

If the pulley or crank is moved towards the ' Off ' position, valve K is brought nearer to seat L, so that the steam is cut off sooner, because tube E has to expand less to bring valve K on to its seat L.

If the pulley or crank is again moved towards the ' On ' position, the opposite effect takes place. The temperature of the heater is therefore regulated to a nicety by manipulating the crank or pulley.

When the pulley or crank is moved right over to the ' Off ' position, the valve K is brought on to the seat L, thus shutting off the steam ; and as the heater cools down and tube E contracts, the valve K is kept up against its seat L by the pressure of spring X.

It will be seen, therefore, that a variation of pressure in the main pipe does not affect the temperature of the heater, which is controlled entirely by the position of the pulley or crank. As the steam in the heater is never at more than atmospheric pressure, the highest possible temperature therein is 212° F.

A strainer is provided to prevent the passage of foreign matter into the heater. The cap P should be unscrewed and the strainer cleaned when necessary.

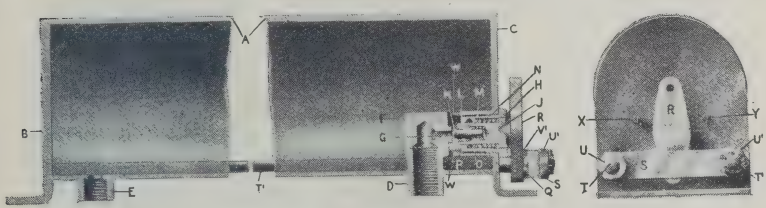

FIG. 29.

Another type of heater is illustrated in fig. 29. In this case the thermostatic control is obtained by expansion and contraction of the main heating tube against two external solid rods which are fixed to one end of the main tube and cause movement of the valve in relation with the seat of the valve mounted in the main tube.

The end covers B and C, the steam inlet connection D, and drain connection E are welded to tube A, and the valve casing F is welded to cover C. The valve seat G, and bush H, are screwed into casing F. In bush H slides a stem J, carrying valve K, which is held in position by a nipple L, and pressed towards the left by spring M. Another spring N is interposed between gland O and a shoulder in stem J, and serves to keep the gland tight against packing P, and also to keep projection Q on lever R in contact with plate S. Two rods, T and T^1, are fixed in cover B, and extend outside and parallel to tube A, through holes in plate S to which they are attached by nut U and castle nut U^1, and lock nuts V and V^1. Steam enters at D and passes into the heater at openings W. Water of condensation escapes to atmosphere through E.

When tube A is hot it expands, and, as the external rods T and T^1 remain cooler, the nuts U and U^1 press against plate S and cause stem J to slide towards the left, pressing valve K against its seat. As tube A cools it contracts, and seat G is withdrawn from valve K, allowing steam to enter again.

The temperature control operates in exactly the same way as in heaters described above—*i.e.* the plate S is adjusted out of parallel with the end cover so that rotation of lever R causes stem J to move in or out of bush H. This adjustment is set before the heater leaves the works, and further adjustment in service should be confined to moving the nut U and its lock nut V (behind plate S) very slightly.

If necessary at any time, the valve can be removed from the heater while the latter is in position by removing the 'On' and 'Off' stops X and Y, turning lever R clear of plate S and withdrawing stem J.

The Westinghouse system of heating is in use on the chief railways in the United Kingdom and on many railways in foreign countries, including some of the coldest in the world.

BRAKES.

Action of Brakes.

f = proportion which resistance produced by brakes bears to weight of train.

v = speed in feet per second.

V = speed in miles per hour.

Distance in feet in which the train is stopped on level $= \frac{v^2}{64{\cdot}4f} = \frac{V^2}{30f}$.

Brakes self-acting on all the wheels, $f = {\cdot}14$.

Ordinary brakes worked by hand in brake-vans, $f = {\cdot}031$ to ${\cdot}023$.

On gradient *ascending* 1 in n, resistance $= f + \frac{1}{n}$.

On gradient *descending* 1 in n, resistance $= f - \frac{1}{n}$.

Distance in feet for stopping $= \frac{f \times \text{distance on level}}{f \pm \frac{1}{n}}$

Power required by Brakes.

The following results have been obtained as regards consumption of energy with different kinds of air brakes :—1. On city lines, the consumption of energy for excentric compressors was 41·5 watt-hours per car kilom. (66·4 watt-hours per car mile); with geared compressors, 31·2 watt-hours per car kilom. (49·9 watt-hours per car mile); and with motor compressors, 16·16 watt-hours per car kilom. (25·86 watt-hours per car mile). 2. On suburban lines, the consumption for excentric compressors was 22·8 watt-hours per car kilom. (36·5 watt-hours per car mile); with geared compressors, 14·6 watt-hours per car kilom. (23·4 watt-hours per car mile); and with motor compressors, 6·32 watt-hours per car kilom. (10·11 watt-hours per car mile).

The Westinghouse Automatic Brake.

The Westinghouse automatic brake is continuous throughout the train and is operated by compressed air furnished by the compressor and stored in the main reservoir on the engine. This compressed air is fed by the driver's brake valve into the train pipe and, past the triple valves, into the auxiliary reservoir on each vehicle.

The brake is applied by reducing the pressure in the brake pipe, which causes the pistons of the triple valve to move and permit some of the compressed air stored in the auxiliary reservoirs to pass to the brake cylinders, the pistons of which are forced outwards, applying the brake blocks to the wheels.

The brake is released by restoring the air pressure in the train pipe, which causes the triple valves to close the communication between auxiliary reservoirs and brake cylinders and open a port from the brake cylinder to the atmosphere, through which the compressed air escapes from the cylinder. The spring in the cylinder can then push back the piston and withdraw the blocks from the wheels.

The brakes are usually applied by the driver, or in cases of emergency by the guard, but a break-away, or rupture of a hose coupling, or other accident causing an escape of air from the brake pipe, also immediately applies the brakes.

It is recommended that a pressure of 90 lbs. per sq. in. be maintained in the main reservoir, and 70 lbs. per sq. in. in the brake pipe.

Improved Triple Valve.

This valve has been designed to give a closer approach to simultaneous actioe of all the triple valves in a train than heretofore. As shown in fig. 30, the the valve is in the release position and the bulb is open to the atmosphere. When the slide valve 6 is moved in applying the brakes, the bulb 3 is closed to the atmosphere and opened to the brake pipe by the cavity p and port s shown in dotted lines. The local reductions of brake pipe pressure thereby produced by the forward triples in a train cause an earlier action of the rearward triple valves, which results in a more nearly simultaneous braking effect being produced throughout the train in every case of first setting the brakes than heretofore, with a smoother and more efficient brake service generally.

A further improvement, also tending to smooth and even action of all the brakes, is shown in the passage leading from port a in the seat of the slide valve 6 to the brake cylinder at B. It consists of a removable plug 13, perforated with holes w and x, which are always open, and an additional hole y carrying an automatic check valve 14, supported by a spring 15. It is so arranged that, when the brakes are first set, the automatic valve is opened against the spring resistance by the excess of air pressure above it, so that the hole x controls the rate of flow of air to the brake cylinder: as the air pressure on the under side of the valve increases, the spring closes the valve, when the smaller holes w control the rate of flow to the brake cylinder. The diameters of the regulating holes w and x are made proportional to the diameter of the brake cylinder with which the triple valve is to be used. By changing these perforating plugs, the same pattern of valve is thereby suited to cylinders of various sizes.

The bulb at the bottom of the triple valve is made in different sizes, proportioned in content to the volume of the brake pipe of the vehicle on which the valve is to be used.

A separate passage a^1 is provided in the triple valve body from brake cylinder to slide valve 6 for the air to escape from the brake cylinder on releasing the brakes. The rate of release is controlled as heretofore, by a nipple screwed into the outlet hole c in the triple valve body.

Driver's Equalising Brake Valve.

The principle of this brake valve, fig. 31, is not to allow the driver in ordinary applications of the brakes to discharge air directly from the brake pipe, but from a small reservoir connected with chamber T of the valve. The reduction of air pressure, thus effected in the reservoir, is then at once automatically and properly repeated in the brake pipe by means of a small equalising piston, 11, placed between the air in the chamber T, and that in the brake pipe E. The piston moves in accordance with the variations in pressure above and below it, and governs an exhaust valve U in such a manner that the air pressure in the brake pipe must always equalise with that in the small reservoir connected with the valve chamber T. Even if the exhaust of air from the brake valve reservoir is abruptly stopped by the driver, the discharge valve U is always gradually closed by the piston, when equilibrium of pressure is established throughout the train. The equalising device, therefore, will under all circumstances provide for a uniform reduction of the pressure in the main brake pipe, thus ensuring a uniform application of the brakes to all the vehicles in the train.

The compression of air is effected by a compressor (Westinghouse), a description of which is given in Section XXIII.

Pipe Couplings.

In the connecting-pipe *coupling*, which is shown by fig. 32, the two halves of couplings, 1, are exactly alike, and an air-tight joint is formed by means of the rubber packing-ring, 3, 1 in each, which rings face each other when the couplings are united. The air-pressure in the

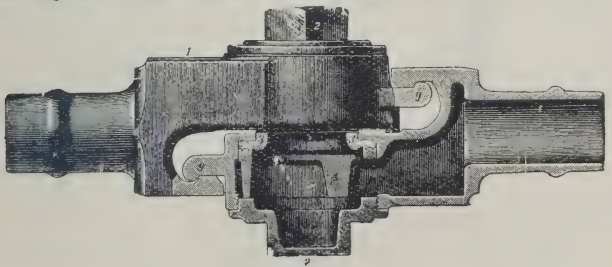

Fig. 32.

couplings tends to force these rings towards one another, so that the joint becomes tighter with increase of pressure. The tendency of the air-pressure in the couplings is also to force them apart in a direction at a right angle to the line of the india-rubber hose-pipes, and, consequently, the greater the pressure, the more firmly are the couplings held together by the projecting piece, g,

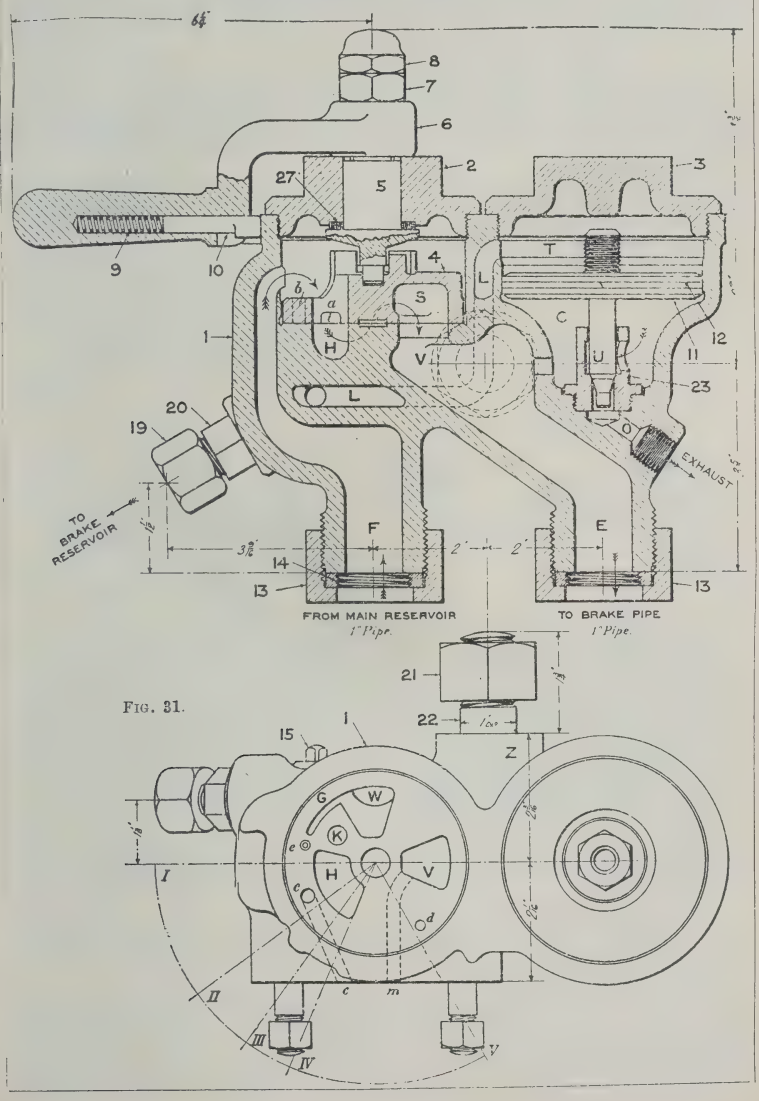

FIG. 31.

of each coupling, which fits in a corresponding groove of the other coupling. No damage is done if the couplings be drawn apart forcibly by the separation of the train, as the rubber rings, 3, 3, are forced into their respective couplings far enough to permit the projections to disengage from their grooves. These couplings are united by simply placing them face to face at right angles, the stop-pins being on the under side, and then turning the projection of the one into the groove of the other.

The Vacuum Automatic Brake.

The Vacuum Automatic Brake is applied by admitting air to the brake cylinders through a continuous brake pipe, and released by withdrawing the air. To charge the brake cylinders, air from above the piston is withdrawn through a non-return ball valve to below the piston and thence direct through the brake pipe to a high-speed rotary exhauster in the case of an electric locomotive, or an ejector if a steam locomotive.

A service brake application is made by the driver admitting air to the brake pipe through a valve on the locomotive, and atmospheric pressure entering the brake cylinder below the piston acts against the vacuum above the piston and applies the brake at a pressure proportionate to the reduction of vacuum in the brake pipe. Air is prevented from entering the evacuated space above the piston by the non-return ball valve.

An emergency brake application may be made with the guard's van valve at rear of train, or a slow brake application by the passenger emergency valve fitted on each carriage. The brake is automatically applied throughout the train if an accident occurs sufficient to part the couplings.

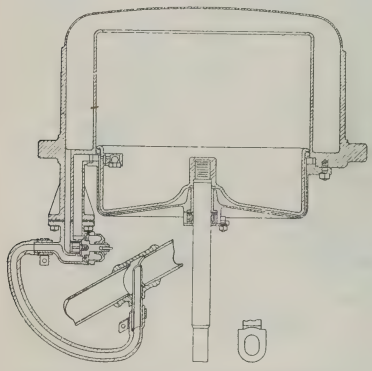

FIG. 33. "Prestall" Wrought Steel Vacuum Brake Cylinder with internal ball valve and external release valve. Piston in release position. Air above piston is exhausted through the internal ball valve. The brake pipe connection to cylinder (shown in section) is provided with a siphon to prevent condensed moisture from being drawn into cylinder.

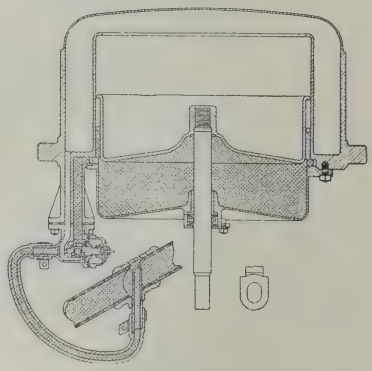

FIG. 34. "Prestall" Wrought Steel Vacuum Brake Cylinder with external ball valve. Piston in 'brake on' position. A brake application is made by admitting air to the shaded portion below piston. The non-return ball valve prevents air entering the space above piston.

Passenger trains are generally operated at 20-in. vacuum, but a few railways use 24-in. vacuum; and freight trains at 20-in. vacuum, or 16-in. vacuum on long trains where high vacuum is difficult to maintain.

Brake cylinders are either of the combined type with the vacuum chamber forming the outer casing of the cylinder (see figs. 33 and 34) or separate type with an independent vacuum chamber. In the former case, the cylinder is connected to the brake pipe by a single branch valve, and in the latter case a double branch is used, the second branch connecting the vacuum space above piston with an independent vacuum chamber.

The ball valve is housed either inside the piston as shown in fig. 33, or in the casing of a detachable valve as fig. 34. The former type of valve is less liable to leak through grit being drawn on to the valve seat, and it possesses a further advantage that when the piston moves upwards during a brake application the port in the wall of the piston (leading to the ball valve) passes to the vacuum side of rolling ring, and thus isolates the valve and cuts off a possible source of leakage that might render the brake inoperative. The poppett type release valve (see fig. 33) used on cylinders with an internal ball valve, effects a more rapid manual release of the brake than is

possible where the ball valve (see fig. 34) combines the functions of check valve and manual release valve as with the externally housed ball valve.

The tendency to reduce deadweight wherever possible, and the use of higher tensile materials in the construction of rolling stock has led to the introduction by the *Westinghouse Brake & Saxby Signal Co.*, of brake cylinders made entirely from pressed steel. These are 30 to 40 per cent. lighter than cast-iron cylinders and possess greater resistance to fracture or breakage. These cylinders, known as the "Prestall" wrought steel cylinders (figs. 33 and 34) have a detachable base for the easy renewal of the rubber rolling ring packing between cylinder and piston, the total detachable weight being 50 per cent. less than the cast-iron type in which it is necessary to remove the entire cylinder from casing in order to renew the rolling ring. The piston rod is guided by a gun-metal bush and rendered airtight by a rubber gland arranged so that atmospheric pressure acting on the outside diameter of the gland forces it with an even pessure around the piston rod. The rubber gland is easily renewed without dismantling the cylinder by simply unbolting the steel cover-plate forming the gland cap.

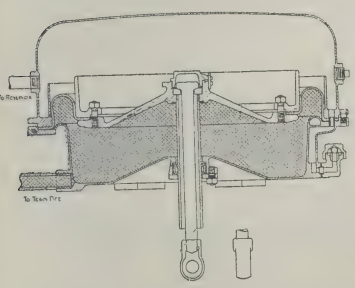

FIG. 35. "Prestall" Wrought Steel Diaphragm Cylinder. The rolling action of the diaphragm between the vertical flanges is shown with the Piston at 'brake on' position; the shaded portion represents atmospheric pressure.

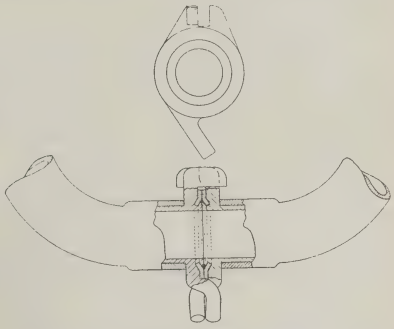

FIG. 36. Vacuum Hose Coupling. *Above*, End Elevation; *Below*, Sectional side Elevation.

In all cylinders with rolling ring packing a certain amount of leakage is liable to occur after the rolling ring has become worn, and to avoid this, certain railways use a cylinder with a reinforced rubber diaphragm, since the vacuum can be maintained above piston for a longer period with a diaphragm than is possible with the rolling ring packing. This is an important feature for railways with long gradients, since it is impossible to recreate the vacuum above piston without first releasing the brake. The "Prestall" wrought steel diaphragm cylinder, fig. 35, is provided with a vertical guide flange on the piston follower, and a corresponding flange in the dome of the cylinder, so that the diaphragm rolls between these two walls and the atmospheric pressure beneath the diaphragm is confined to a vertical path in the line of piston travel. This enables a longer and more powerful stroke than is possible when the diaphragm is not so guided.

The continuous brake pipe is generally 2-in. bore, but a few narrow-gauge railways use 1½-in. bore. The brake pipe is connected between vehicles by means of flexible internally armoured rubber hose, at the end of which is secured a metal coupling head with rubber jointing washer. These couplings when connected are held together by the horn at the bottom of coupling, which hooks on to a similar horn on the opposite coupling, whilst a lug and slot at the top of the coupling fits into a similar lug and slot on the opposite coupling, and keeps the bore of the two couplings in register. This coupling in the form approved by the Railway Clearing House is shown in fig. 36.

RAILWAY SIGNALS.

MECHANICAL SIGNALS.

THE WESTINGHOUSE BRAKE AND SAXBY SIGNAL CO., LTD., SIGNALLING SYSTEMS.

Double Wire Working.

In this system two wires are utilised as the operating transmission for the working of point locks, locking bars, derailers, signals, etc. The system, which is employed practically universally on the continent of Europe, has been developed with a view to making it suitable for operation with the British type of signal. A great advantage of the arrangement is the facility with which the operating wires for points, etc., can be run, compared with the installation of the ordinary rod. These operating wires can, if necessary, be placed at a sufficient height to avoid interference with the ordinary use of pathways and sidings. There is a further advantage in definitely pulling the signal to 'danger,' as compared with the gravity method, because it prevents any possibility of an arm remaining in the 'clear' position due to accidental causes, such as freezing of the signal arm or connections; also points and signals can be operated at a greater distance than is possible with the ordinary mechanical system. Points 500 yards from the cabin are well within the limits of working, and thus it is possible with the system to dispense with two interlocking frames where long passing loops or sidings are installed. Fig. 1 (p. 646) shows the type of lever generally used for double wire working. Fig. 2 (p.646) shows a simple form of point mechanism, and indicates how, with a breakage of one wire, protection is given against accidental movement of the points; the catches A and B prevent the driving pulley, to which the operating wires are connected, moving, and, consequently, shifting the points, unless an even tension is maintained in both operating wires; and, of course, functions in both positions of the points. Means are also provided, in case of a breakage of the return wire on signalling systems, for the immediate disconnection of the pulling wire, and the return to 'danger' of the semaphore arm, by gravity.

POWER SIGNALLING.

Electro-Pneumatic.

In the electro-pneumatic system the control and the indication of the operation of the points and signals is carried out by means of electric power, at, as a rule, a moderately low voltage, and at the expense of quite small current consumption, this electric power being required only for the operation of small valve magnets, whereas the actual heavy work of shifting points, signals, etc., is carried out by means of compressed air. This compressed air may be at any pressure, but, as a rule, a pressure of 60 lbs. per sq. inch is chosen. Electric control may be by direct current, or by alternating current.

Simple cylinders are used, to which air is admitted by the electro-magnetic valves before mentioned. The motion of the cylinder being in a straight line, it is unnecessary to provide

special gear for changing the rotary into linear motion, as is necessary with apparatus operated by rotating electric motors.

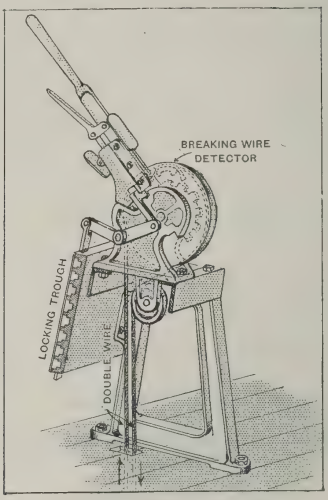

FIG. 1.

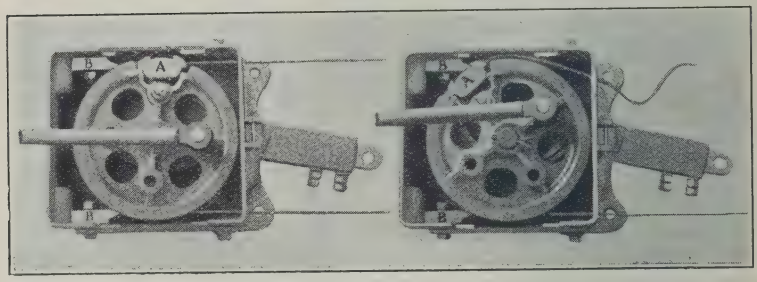

FIG. 2.

All-Electric System.

With the all-electric system, electric power is used both for operation and control. As a rule, for both direct-current and alternating-current systems, a pressure of 100 volts is used, this being applied directly to the motors for the signals or point machines. For operation on direct current, the motors are generally series wound, having two field windings, one of which is connected to the normal and the other to the reverse control wire; the remaining two wires of the field coil are connected to one armature brush, the other brush being connected to the return wire. Application of current to the normal control wire causes the motor to run in one direction, and in the opposite direction when current is applied to the reverse control wire.

Installations operating on this system have been in service at Baker Street (Metropolitan Railway), on the Berlin Underground Railways, and elsewhere, for many years.

With the alternating current system, split phase induction motors are used for the operation of the signals. The point motors are series repulsion type motors, and as the current taken by

these is considerably heavier than that required by direct-current motors exerting the same horse-power, it is generally found advisable to supply current to them from a local transformer, the control from the cabin comprising a polarised contactor and two wires which may be energised with current in one direction, so connecting the field and armature together as to cause the motor to run in one direction, whereas when the current in the control wires and contactor is reversed the field and armature connections to the motor are also reversed, causing it to run in an opposite direction. The current for operating the polarised controller is very small, and comparatively thin conductors can be used between the lever and the controller. This patented system of supplying current locally enables alternating current to be applied in a very simple manner to the heavy work of shifting points.

Point Indication and Detection.

The system now almost universally adopted by the Westinghouse Co. employs a point detector at the points which, with one set of contacts, simultaneously detects both switch tongues and facing point bolt. This point detector can be wired up as a double pole change over switch, to which are connected two wires, which are taken to the signal cabin and operate a relay of the polarised type, so that the relay will be energised in one direction when the points are normal and in the other when the points are reversed. When there is no current on the wires the relay is de-energised. The system can be used either for direct current or alternating current, although the tendency is to use alternating current in all cases.

The arrangement enables all detection of signals over points to be carried out by taking the signal control circuits over the contacts of the relays located in the signal cabins.

Light Signals.

During the past few years there has been a very large development in the use of colour-light signals for daylight work. With these signals the same indication is secured both by night and by day, and signals can be easily distinguished in bright sunshine at 1,000 yards or more. Although the Westinghouse Co. have a number of designs of day colour-light signals, the type which has been most widely installed is that in which systems of lenses, one for each colour, are provided, behind which there are fixed special electric lamps accurately placed at the focal centre of the lens combination, the illumination of the various lamps being controlled by relay or lever contacts. The signal has therefore no moving parts and is very easy of maintenance. The first installation in the British Isles was made on the Liverpool Overhead Railway in 1921, and since that date further installations have been made on the L. & N.E.R. between Marylebone and Wembley, the L.E.R. from Golders Green to Edgware, on the Met. R. between Harrow, Rickmansworth, and Watford, also a very extensive installation for some 200 miles of line in New Zealand. Colour light signals, including a large number of the four-aspect type, have also been installed throughout the extensive area of electrification on the Southern Railway lying between and including Charing Cross, Cannon Street, and London Bridge. In service the indications given by these signals have proved very satisfactory. The latest type of signal developed by the Westinghouse Co. provides a short-range indication in addition to the main beam lights, so as to make the signal indication readily visible to the driver standing directly below and slightly at the side of the signal. With day colour-light signals the alternating current system of control is always used, as it is necessary with such signals to concentrate the source of light in as small a space as possible, and this can only conveniently be done with low-voltage metallic filament lamps. With alternating current, power can be transmitted from a cabin or other source to the signal at 100 volts and transformed down at the signal itself to a low voltage suitable for the lamps.

A development of electric signalling is the operation and control of outlying points and signals. Many such installations are in service in locations where points have to be handled from a greater distance than is possible, or permissible, by mechanical levers and rodding. In some cases the power is supplied by either primary or secondary batteries located near the points, and controlled by wires from the cabin.

Another method is by the hand generator system developed by the *Westinghouse Brake & Saxby Signal Co.*, in which the current is provided by a generator operated by hand when movement of the points or signals is required. Control and interlocking in this case is provided by either a slide lever frame, a small power frame, or even by a standard mechanical locking frame. The distance from which signals and points are operated by this system is, in many cases, more than a mile.

Track Circuits.

Track circuits may be of either direct-current or alternating-current type. In the first, primary batteries are often used with small direct-current relays, but all large modern installations or track circuiting are now carried out on the alternating-current system, in which transformers are used to step down the main supply of voltage to that suitable for use on the track rails, say one to two volts, and an alternating current relay is used. These alternating-current relays are so designed as to make them immune from operation by direct current, and they are therefore suitable for operation on lines where direct-current propulsion is used for electric trains. Where the propulsion current returns to the power station through the running rails, alternating-current track circuits are the only ones which it is possible to use. With these, impedance bonds are necessary at the ends of each track circuit, which impedance bonds are so designed as to allow the direct-current propulsion to pass without hindrance, whilst preventing the alternating-current from passing from one section to the other.

Alternating-current track circuits were first installed in Great Britain on the C.L.R. and G.W.R. about 1910. Since then numerous alternating-current track circuits have been installed in all parts of the world.

WESTINGHOUSE ELECTRO-PNEUMATIC RAILWAY SIGNALLING SYSTEM.

This consists essentially of electrical circuits working in conjunction with a compressed air supply. The electrical system connects the signalman's levers at the cabin with the points and signals, whereby instantaneous response of the signals and points to the motions of the levers is secured, and also an instantaneous 'indication' of the movements of the points and signals is returned to the locking frame. The compressed air of about 60 lbs. per sq. in. pressure serves as the actual power moving the signals and points. The levers in the signal cabin are merely small electrical switches, and they involve no heavy labour on the part of the signalman for their operation. The locking frame, the levers of which are closer together and far less in number than those in the hand system, is provided with two kinds of interlocking—a mechanical system and an electrical system. The mechanical interlocking is practically identical with that used in hand-power signalling systems, excepting, of course, that the parts are very much lighter. The electrical locking consists of a series of electro-magnets connected in the indication circuits from the signals and points; the armatures of these magnets engage with projecting lugs or sectors fitted to the shafts of the levers. By means of this combination of electrical and mechanical locking, the many complicated problems of special locking required by modern methods of signalling are successfully solved. The electrical contacts of the lever shafts, by which the circuits between the battery and the electro-magnetic valves of the point and signal motors are made or broken, consist simply of phosphor-bronze strips, working over contact pieces mounted on an ebonite bushing surrounding the lever shaft. The electric current is usually drawn from a small battery of storage cells, the pressure being about 14 volts. Primary cells are often used, the current required being only about 0·05 ampere per signal or point motor. Small wires made up into cables connect the locking frames with the various point and signal motors.

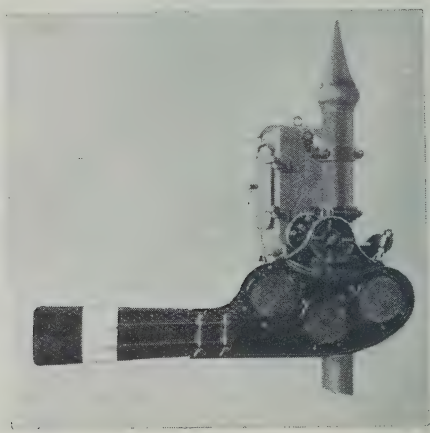

FIG. 3.

The actual work of pulling off a signal or throwing over a set of points is done by a small compressed air-motor fixed close by the signal or point to be operated. The definite, straight line motion of such motors is particularly suitable for the movement of signals and points. The valves controlling the air supply to these motors are opened by small electro-magnets. With this system selection of signals becomes simple, since it is easy to arrange the electrical contacts in such a way that the path of the electric current is made through the signal only which appertains to a route which is set by the movement of certain point levers, and when the signal lever is pulled over that signal only is operated by the electric current; whereas, if other point levers are operated or another route set, the path of the current being changed, another signal is operated when the same signal lever is pulled over.

The pressure of the compressed air used is, as before stated, about 60 lbs. per sq. in. Experience has proved this pressure to be the most suitable for the purpose having regard to the

size of the motors, and the general convenience of installing, operating, and maintaining the system. The quantity of air used does not amount, even at the busiest centres, to more than half a cubic foot of free air per minute per lever.

The electro-pneumatic signal (fig. 3) is fitted direct to the post, and is designed for either two- or three-position working. The air cylinder C (see fig. 4) operates the arm to the 'caution' or

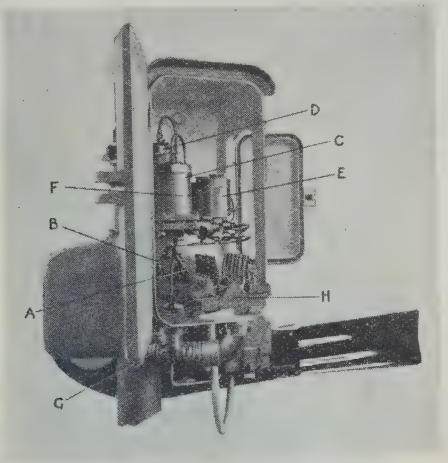

FIG. 4.

45° position, under the control of electro-pneumatic valve E, through crank A, which rotates the spindle on which is mounted the semaphore arm. This arm is operated to the 'clear' or 90° position by the air cylinder D, under control of electro-pneumatic valve F, through crank B. The apparatus is so designed that the 90° position cannot be reached by the semaphore arm unless the electro-pneumatic valve controlling the 45° position has first been energised. This arrangement greatly simplifies control wiring. Each signal has an internal circuit controller H, which provides contacts for controlling such external circuits as for indications, repeaters, etc. The return to the 'danger' position of the semaphore arm is by gravity, immediately the pressure is cut off, and the cylinders exhausted, by the electro-pneumatic valves. The exhaust of air is choked by an exhaust nipple which provides a cushioning effect, so that the arm will not drop too heavily.

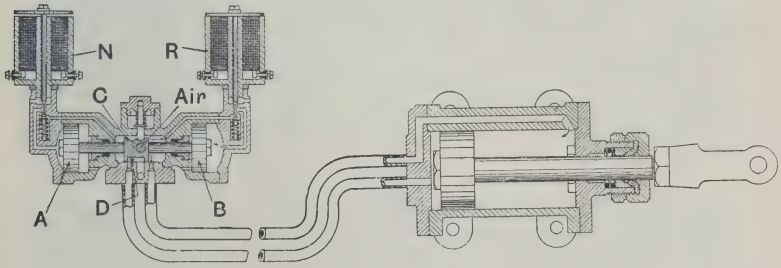

FIG. 5.

The point motor, fig. 5, consists of a double-acting cylinder working horizontally, and is usually installed outside the track, alongside the points. Compressed air is admitted to this cylinder by the point valve, which is usually mounted on a post near-by and connected to the cylinder by two

pipes. The point valve consists of a slide valve C moved by pistons A and B, these pistons being in turn controlled by electro-pneumatic valves N and R respectively, which admit air (or exhaust it) behind pistons A and B, according to which valve is energised. The chamber in which the slide valve is located is under constant air pressure, and when the slide valve is moved to right or left it uncovers one or other of two ports which communicate direct with the back or front ends of the cylinder. At the same time the covered port is bridged by a cavity on the face of the slide valve to a third port open to atmosphere.

The latest development is the point valve style C (fig. 6), which employs a third electro-pneumatic valve, the purpose of which is to lock the slide valve into position, and to cut off the air supply after each operation of the cylinder. This arrangement enables metal-packed pistons to be used in the point cylinder, and also economises in compressed air, as the cylinder is under air pressure only while the movement is taking place.

When the style 'C' point valve is used it can be arranged so that should the point tongues be accidentally or deliberately displaced, air is automatically applied to the point cylinder so that the tongues will be closed again.

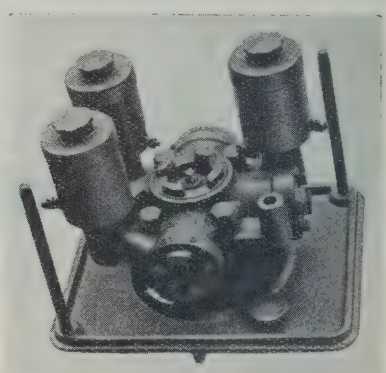

FIG. 6.

Westinghouse electro-pneumatic signals are also largely used in connection with automatic signalling, both on steam and electric traction roads. For this purpose the running rails are divided into suitable sections or blocks which are electrically insulated from one another: the presence of a train or any vehicle in a block keeping the signals controlling the entrance to that block at danger. The signals are not cleared to admit a second train until the first train has cleared the block by a certain distance, depending upon the braking distance required by a train.

Such installations are largely used in America, there being nearly 10,000 signals of this type in operation. In Great Britain complete installations have been working for several years on the Metropolitan Railway, the Metropolitan District Railway, the London Electric Railways (consisting of the Baker Street and Waterloo; Great Northern, Piccadilly and Brompton; and Charing Cross, Euston and Hampstead Railways), the Central London and the East London Railways. These installations deal with a service of forty trains per hour, and have the additional protection of a train stop at every signal location which automatically applies the brakes on a train should it overrun a signal at danger.

The electro-pneumatic signalling apparatus, both for power-operation of points and signals and for automatic signalling, is manufactured and supplied by The Westinghouse Brake and Saxby Signal Co., Ltd.

'CREWE' ALL-ELECTRIC SYSTEM.

The Railway Signal Company, Ltd., are the manufacturers of a system, of which there are several installations on the London Midland and Scottish Railway (North Western Section)—hence its name—of operating points and signals by electricity.

Fig. 7 shows the locking-frame, and it will be seen that the levers are in two tiers, those, *a*, in the upper tier taking odd numbers and, generally, working points, and those, *b*, in the lower the even numbers and, generally, working signals. To each lever is connected a down-rod *c* to which, immediately under the signal-box floor, are coupled cranks. These actuate the interlocking tappets in the usual interlocking-boxes. At the lower end of the down-rod is connected the switch *d*, the carbon contacts of which join, when the lever is moved, switches *e f* and *g h*, and so cause power to be sent to the points or signal as the case may be.

FIG. 7.

As in other power-signalling systems, the full stroke of a point lever from normal to reverse and from reverse to normal, and the complete stroke of a signal lever from the 'off' to the 'on' position, cannot be made until an indication is received that the operation set up by the initial movement of the lever has been completed. This, in the 'Crewe' system, is achieved by the check lock j attached below the switch. On the check lock j are two lugs k^1 k^2 which engage pawls l^1 l^2, the armatures of which can be attracted by the magnets m^1 m^2. When a point lever is moved, say, from normal to reverse, the down rod is raised and the lug k^2 on the check lock will then abut against and be stopped by the pawl l^2, but as soon as the current set up by the switches above has done its work, the return indication current energises the magnet m^2, so that the pawl p^2 is attracted and frees lug k^2, consequently the lever can then be pulled the remainder of the stroke. When the points are being restored to normal the down-rod descends and lug k^1 is then stopped by pawl p^1 until magnet m^1 is energised. When the points are reversed the switch d has its contacts on switches e and g, and when normal on switches g and i.

Fig. 8 is a plan and elevation of the lay-out of a pair of facing points. The motor (see also fig. 9), which requires a current of 20 amperes and 100 volts, is fixed in a cast-iron box below the rail level. The motor a (fig. 9), by means of a worm, drives the worm wheel b, fixed loose on the same shaft as the cam wheel c. Movement is transmitted to the cross shaft by means

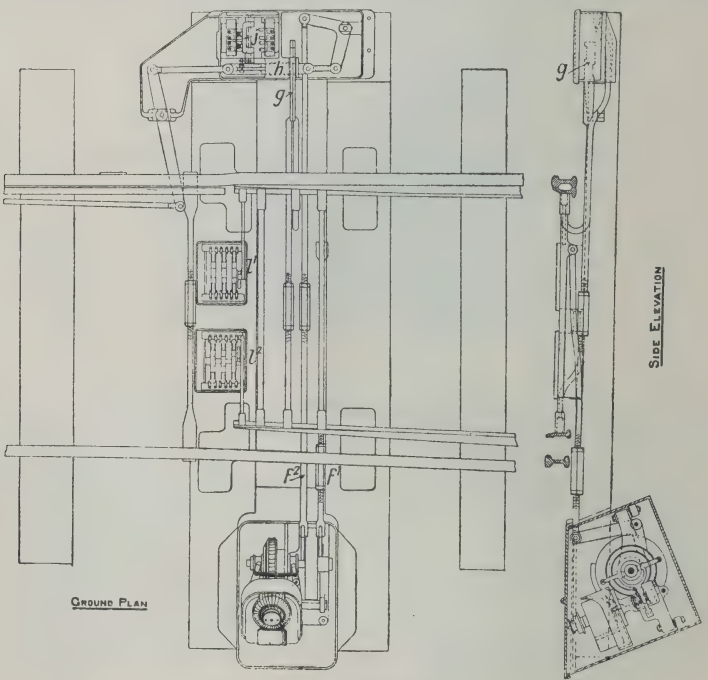

FIG. 8.

of one or other of the clutches d^1 d^2, which are right- and left-handed, so that if the worm wheel turns in one direction the right-handed clutch is engaged and if in the other direction the left-handed clutch. On either face of the cam wheel c is a cam-shaped slot of irregular contour in which works a roller attached to a crank, e. The crank on one side works the points by means of the rod f^1, and the other crank actuates the plunger and locking bar by means of rod f^2. Each point has an extension g, suitably slotted on the upper side for one position of the points and on the lower side for the other position of the points. Both extensions and, therefore, both switches of the points, must be accurate in their position or the plunger h will not pass through them. To the end of the plunger is connected a rod leading to the locking bar. On the upper side of the plunger

are guides that move over a short lever and place the contact maker j in or out of contact with the springs k^1 k^2. The latter are connected to the magnets m^1 m^2 of the return indication in fig. 7 and cause pawls l^1 l^2 to be attracted and allow for the down rod c to complete its upward or downward movement and for the switch d to make contact with e g—if an upward movement—or with g i if a downward movement. This cuts off the current from the motor. But as will now be readily understood, this cannot occur until the plunger is shot and the switches held, nor can the plunger be shot unless and until the switches are in their correct position. Further detection is given by means of the contacts l^1 l^2, which are in the circuits to the signals concerned. The switches for these contacts are rotated by means of short rods connected as near as practicable to the 'nose' of both point switches.

Signals in the 'Crewe' system, whether semaphore signals or the dwarf signals used in shunting operations, are changed from the 'danger' to the 'clear' position by means of a long-pull magnet m, fig. 9. A current of about 15 amperes and 100 volts is required for a fraction of a second to clear a signal, which current is then passed, by means of the switch n, through a resistance, and about 2 amperes is enough to hold the signal at 'clear.' When the lever in the signal-box is replaced partly to normal the current supply to the signal is completely cut off and the arm goes to danger by its own gravity. When the signal is fully 'on' the switch n sends the return indication and allows for the lever to complete its stroke. No return indication is necessary to show that a signal has gone from 'danger' to 'clear.' What is of importance is that it has gone from 'clear' to 'danger.'

SYKES ELECTRO-MECHANICAL SYSTEM.

About 2,000 levers have been installed in the electro-mechanical system of the W.R. Sykes Interlocking Signal Co., Ltd., wherein all signals are actuated by electricity, the circuits for which are completed by a small slide being drawn forward or pushed back, and all points are moved by the usual mechanical lever, elevations of which are given in fig. 10

The slide a carries contact pieces b^1 b^2 which, when the slide is drawn out, put springs c^1 c^2 into contact with the plate d. This completes the circuit to the signal governed by the lever by means of wires passing through the box e. When it is necessary to control the movement of a slide, e.g., from another signal-box, or by a fouling bar or track-circuit, a pin rests normally in the slide which can only be lifted when the magnet f is energised. The slides are interlocked as in a mechanical frame, but on a miniature scale. The slide itself acts as its own tappet, and the locks are in the locking-boxes g g.

The tappet of the mechanical lever is h, and a stud h^1 turns the shaft h^2, and so, by a stud h^3, actuates a co-acting tappet in the electrical part. By this the mechanical levers and electrical slides are interlocked.

By an ingeniously arranged escapement wheel the movement of the mechanical tappet is only 2 ins., the same as the electrical slide. A lock j in the tappet k holds point levers when required until they are freed by the lock being lifted out of the tappet by the magnet l being energised.

Sykes Railway Signalling Devices.

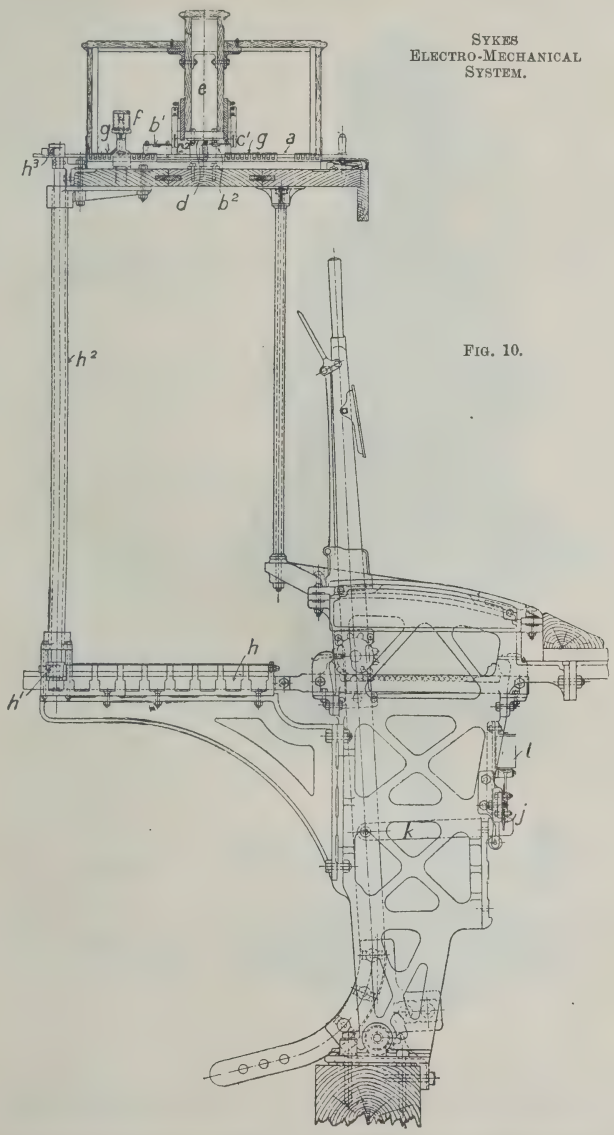
For block signalling, three wire and one wire instruments of various patterns are made, a special system, extensively used on the Southern and L.N.E. Railway's suburban lines being also supplied. In this latter arrangement the signal levers are directly interlocked with the block instruments, so that they must be worked in unison. The system is peculiarly adapted to a heavy suburban or mixed traffic, as it can be worked very rapidly with ease and safety. Modifications have been supplied to Colonial lines, and in recent years a new lock-and-block system called the Style 'L' has been devised, and is used in India, Argentina, Brazil, Cuba, Ceylon, Siam, and elsewhere. The apparatus has been designed with a view to eliminating the difficulties often experienced with native signalmen. An alarm signal gong is sounded whenever a movement has not been made at the right time, and continues till the omission is rectified, while the train itself automatically announces its departure ahead if the signalman fails to do this. In addition, the new system is free from the old cancelling key difficulty, it being impossible to reset the instruments if a train is in the section.

A lock-and-block system for single line working has been devised which enables long and short sections to be worked with great facility, without the complications found in staff and tablet systems. A 'switching-out' instrument can also be used with these systems, and has been adopted by several lines. Messrs. Sykes also make a special instrument for non-crossing block posts, where staff or tablet apparatus is in use.

The 'Intermediate Sidings Key' apparatus is an improvement on the 'Annett' Key, as it enables the key to be taken to either end of the section after use, whereas with the older apparatus it must return to the issuing point. The sidings key instrument may be looked on as a staff instrument for trains using the siding only.

Electrical point and bolt detectors, by means of relays, with interlocked armatures, enable the position of the points to be continuously repeated in the cabin, the electric locking circuit being local.

Electric lever locks are made for track circuit locking and other electrical controls, and also for block instruments. Rail contacts, operated by the deflection of the rail itself—the usual method—or constructed as depression bars worked directly by the wheels, are made.



SYKES
ELECTRO-MECHANICAL
SYSTEM.

FIG. 10.

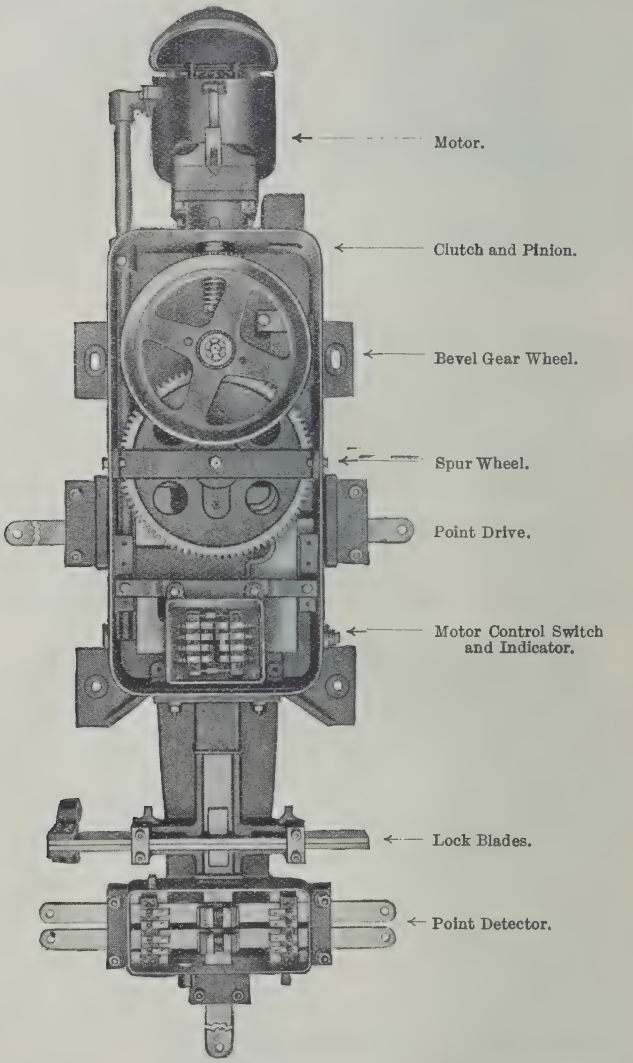


FIG. 11.—British Power Railway Signal Co.'s patented Point Operating Machine.

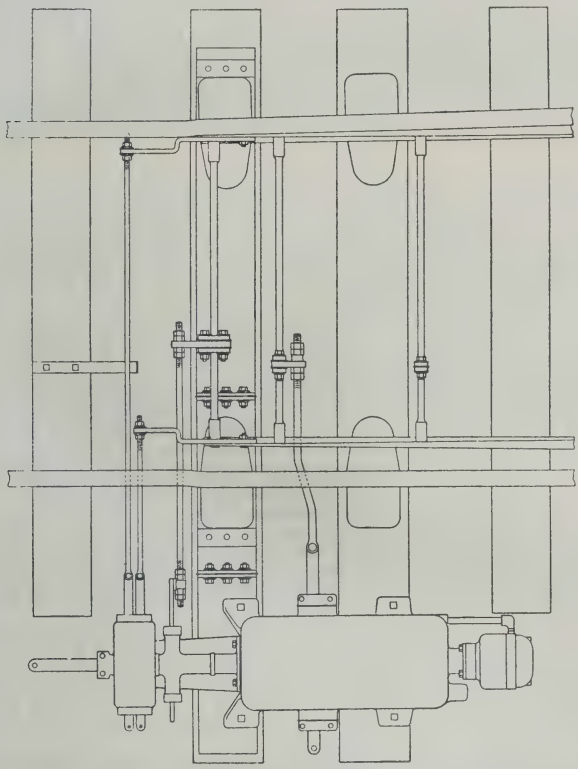

FIG. 12.—Low-Volt Quick-Acting B.P. Point Operating Mechanism, with Outside Point Lock and Detector Attachment.

For 'track circuiting' Messrs. Sykes devised some years ago a flange type joint, which is highly efficient and still in use.

What is termed 'intermediate signalling' is now coming into favour, to enable simple intermediate block posts to be abolished, and the signals controlled from the adjacent cabins. Track circuiting and, generally, lock-and-block control are used for this, and the plan enables considerable economies to be effected. Messrs. Sykes have laid down several installations, a recent one being near Manchester, on the Cheshire Lines.

Recently a new system of signals for single line tramways has been designed and put into service on the Mumbles Rly. The signals are operated from the 700-volt trolley circuit by special contactors, with which the trolley itself makes contact, and exhibit red and white transparent discs, illuminated from behind. The indications are exceedingly clear and have greatly facilitated the single line working on the line. In addition, a novel form of facing point lock has been applied to the points at the ends of the loops, which are spring points, normally bolted. The bolt is withdrawn just before a car passes through in the trailing direction by a depression bar actuated by the treads of the wheels, and returns to the locking position when the point tongue springs back. A shearable piece is incorporated in the bolt to protect the points should the bar become disconnected. A colour light signal, having red and green lights, faces towards the single line, and exhibits a green light when the points are closed in position and bolted. The working of the whole arrangement is automatic.

LOW-VOLTAGE POINT MOVEMENT.

(*The British Power Railway Signal Company, Ltd.*)

The Low-Voltage Point Mechanism, which is used to a considerable extent on single lines, makes it possible to control both points and signals from a distance, and affords a convenient and economical means of operating many outlying points where the cost of a pointsman or interlocking frame would be prohibitive.

The main feature of the arrangement is that the actual operating battery consists of a small set of primary cells or accumulators situated somewhere near the points. Current is supplied to the point motor through control relays, which operate with a fractional amount of current, and can therefore be governed by small line wires over long distances.

Indicators provided in the operator's cabin show at all times the position of the points, and any irregularity of working is immediately detected. Each mechanism box is supplied with a special metal crank handle, which, when fixed on to the shaft of the motor, can be used to mechanically wind over the points for maintenance purposes or in case of battery failure. When not in use, and resting in its normal place in the mechanism case, this handle forms part of the electrical return circuit common to both the operating control relays, and also the signalman's indicators, so that the latter set themselves to show something amiss immediately the handle is removed from its proper place. The control relays are also rendered inoperable.

If track circuit is provided, as in a complete scheme, this can be utilised to prevent a movement of the switches while vehicles are fouling any part of the crossover.

The controlling switch can be placed in any convenient position, and it is sometimes found useful to fix this in the telegraph or stationmaster's office, for instance, when there is only one pair of points for a siding, passing loop, or other purpose in the vicinity, but of course it can also be fixed to and operated by an ordinary lever interlocked with other signals and point levers if required.

Fig. 11 shows the British Power Railway Signal Co.'s patented point operating machine fitted with Point Lock and Point Detector outside attachment. This machine is standard for high (110 v.) or low voltage (20 to 30 v.) operation.

The main operating mechanism consists of a chain of gears comprising :—A bevel pinion fitted with safety clutch device and meshing with a bevel wheel keyed to a spur pinion, this in turn meshing with the main spur wheel. This spur wheel is fitted with roller devices for driving the power bars.

The motor is series wound, enclosed in a substantial weather-proof case. Provision is made for hand operation of the points by means of a crank handle, which requires an isolating switch contact arm to be swung out of the way before the handle can be placed in position.

Figs. 11 and 12 show one of a large number of variations or combinations of machine fixing and point connections.

ALL-ELECTRIC POWER SIGNALLING.

(*The British Power Railway Signal Company, Ltd.*)

Amongst signal engineers the all-electric system of point and signal operation has met with more favour generally in recent years than those systems, such as the electro-pneumatic, where two sources of power are required for operation. Each system has its own advantages and disadvantages, and the choice between the two systems depends on the circumstances at the particular station or yard where an installation is contemplated.

The system of all-electric signalling adopted by the British Power Railway Signal Company, Ltd., is based on the principles of dynamic indication in combination with an automatic stroke completion movement of the signal or point lever, and also a complete cross protection system. The following is the arrangement :

Locking Frame.

The lever slides are arranged in easily detachable units at 3 in. pitch, each slide having cam-shaped slots cut therein for the operation of the interlocking, which is arranged vertically at the front of the machine. A further cam slot is also cut in each lever for the purpose of obtaining the automatic lever movement by solenoid action acting on the diagonal portion of the cam slot for indication purposes.

An extension of the lever slide carries a contact maker which makes and breaks with ' normal ' and ' reverse ' contact springs for operation of the points and signals. A horizontal rod extension from the lever slide operates the combination circuit closer arranged vertically at the back of the frame for the control of the various circuits. The safety and indication selector relays are fixed conveniently at the back and below the lever slides, as also the polarised relays for cross protection purposes.

Point Mechanism.

The power point mechanism comprises a 110-v. motor in weatherproof casing and bolted solidly to the gear-case. The motor operates the train of spur gears and the main cam gear for unlocking, throwing the points and relocking. A friction clutch is provided to protect the mechanism from shock in case of obstruction. A pole-changing device is provided, all self-contained in its own casing within the main gear-case. The pole-changer is required for the changing of the motor connections at the end of each point operation ; this is effected by a cam slot on the lock bar connection, and in addition is also operable by solenoid magnets, in order that the points may be reset in their previous position in the event of any obstruction in the points. Connections from the lock bar may be arranged to work a combined facing point lock with point and lock detector, or the design of point mechanism is arranged for an outside lock or combination of out-side lock and point detector attachment bolted securely to the end of the mechanism casing to meet varying conditions and requirements. Energy for the dynamic indication stroke of the lever is obtained by the overrun of the point motor after the completion of the movement of point function, and in addition the generated indicated current provides an automatic snubbing action to the motor and all parts are brought to rest without shock. Two wires are used for operation, ' normal ' and ' reverse,' and these are used for the return indication current ; the ' normal ' operating wire is used for the ' reverse ' indication, and the ' reverse ' operating wire for the ' normal ' indication.

For detection, one ' normal ' and one ' reverse ' wire is used.

Signal Mechanism.

The signal mechanism comprises a 110-v. motor with a train of gears operating a circuit controller and main driving shaft. A spring attachment is operated by this driving shaft and is placed under tension when the signal lever is operated. When a train enters a track section govern-ing the signal the operating current is broken and the signal falls by gravity to the ' stop ' position. The spring tension comes into action, when the lever is returned to ' normal,' for the purpose of rotating the motor armature, which generates the dynamic indication current and automatically completes the indication stroke of the lever.

The design of mechanism is similar for running signals or dwarf signals ; for the latter an alternative signal of the solenoid type is sometimes used, in which case battery indication is provided.

D.C. OR A.C. LOW-PRESSURE ELECTRO-PNEUMATIC SIGNAL SYSTEM.

The British Power Railway Signal Co., Ltd., specialises in d.c. or a.c. electro-pneumatic systems for terminal or through stations, in which the principles of the automatic indication of the stroke completion of the lever, and cross protection, are retained, as in the All-Electric Signalling System. The points are operated by 8-in. diameter cylinders controlled by electro-pneumatic valves, the operating air pressure varying from 15 to 20 lbs. The signal operating cylinders are 4 in. diameter.

For gravity or sorting yards, the point operating cylinders are 7 in. diameter and are controlled by electro-pneumatic valves energised from a push-button machine placed in the control cabin.

Mechanically Operated Points.

The limit of distance from levers working points to be 350 yds., unless the points are power worked and occupation of the lines is electrically indicated in the signal-box, in which case the distance may be indefinitely extended. (*Ministry of Transport.*)

SECTION XIII

PART IV

RAILWAY EXPENDITURE AND RECEIPTS.*

Financial Statements.

The capital expenditure of the railways in Great Britain at 31st December, 1929, amounted to 1,222,851,206*l.*, as compared with 1,216,234,299*l.* at the end of 1928, an increase of 6,616,907*l.* Capital receipts at 31st December, 1929, amounted to 1,170,532,425*l.*, the amount received during the year 1929 being 2,098,395*l.* The excess of capital expenditure over capital receipts was thus increased from 47,800,269*l.* to 52,318,781*l.*

The gross receipts from railway working amounted to 195,409,523*l.*, compared with 194,005,049*l.* in 1928, a increase of 1,404,474*l.*

The amount appropriated for the payment of interest and dividends in 1929 was 48,355,050*l.*, as compared with 44,873,928*l.* in 1928, representing 4·13 per cent. upon the receipts from capital issued as compared with a corresponding figure of 3·84 per cent. in 1928.

The Reserves and Depreciation Funds of the companies, which in 1928 amounted to 80,873,477*l.*, were reduced to 79,876,621*l.* in 1929.

Way and Works.

Mileage of Lines.—The total length of road open for traffic at the 31st December, 1929, was 20,419 miles, a increase of 10 miles during the year. Expressed as single track, the total mileage of running lines was 37,169 miles (an increase of 26 miles) and of sidings 15,514 miles (an increase of 87 miles), representing a total increase of 113 miles during 1929.

Rolling Stock.

Locomotives.—The number of steam, electric, and petrol locomotives owned, excluding those employed solely on departmental services, at the 31st December, 1929, was 23,454, a decrease of 212 during the year.

Coaching Vehicles.—The number of electric and steam or petrol rail motor vehicles showed an increase of 344 during the year, and of carriages worked by steam power, a decrease of 1,062.

The total number of passenger-carrying vehicles owned was 51,243, a decrease of 718, and the seating capacity of these vehicles was 2,800,272, a decrease of 8,851.

The stock of Pullman cars in use increased from 204 to 229.

Merchandise, Mineral, and Railway Service Vehicles.—The number of merchandise and mineral vehicles owned at the 31st December, 1929, was 700,093, a decrease of 5,988 during the year. The total tonnage capacity excluding brake vans (13,527) was 7,690,405, a increase of 16,147 tons. The average capacity per wagon rose from 11·08 tons to 11·20 tons.

The service rolling stock vehicles decreased during the year from 49,520 to 47,304.

---

* 'Returns of the Capital, Traffic, Receipts, and Working Expenditure, etc., of the Railway Companies of Great Britain for the Year 1929.' (Ministry of Transport. H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2. Price 6*s.* 6*d.*)

Operation.

Engine-Mileage.—The total engine-miles run increased by 14,312,955, or 2·39 per cent. Coaching train-miles were higher by 2·20 per cent., freight train-miles increased by 3·28 per cent., coaching and freight shunting-miles increased by 2·7 per cent., and other miles (assisting light and departmental) increased by 1·26 per cent.

Fuel and Lubricating Oil Consumed.—For all services combined the consumption of coal increased from 53·55 lbs. to 54·02 lbs. per engine-mile, and the consumption of lubricating oil increased from 6·62 pints to 6·63 pints per 100 engine-miles. The total tonnage of coal consumed and pints of lubricating oil used by steam locomotives and steam rail motors on standard gauge railways were 13,413,308 tons and 36,947,035 pints respectively, as compared with 13,051,812 tons and 36,200,671 pints in 1928.

Wagon-Load.—The average wagon-load for all descriptions of freight increased from 5·54 tons to 5·64 tons, and the average train-load increased from 127·09 tons to 130·90 tons.

Traffic.

Passenger Traffic.—The total number of ordinary and workmen's journeys increased by 3·37 per cent.

The total number of passenger-journeys, including season-ticket holders on the basis of 600 journeys per annual ticket, increased by 2·30 per cent.

Parcels and Miscellaneous Traffic.—The gross receipts from parcels and miscellaneous passenger-train traffic (excluding parcels post and mails) on standard gauge railways were 14,316,990*l.*, an increase of 0·81 per cent. compared with 1928.

The average receipt per coaching train-mile from passenger-train traffic, including mails, parcels, etc., and other merchandise conveyed at passenger train rates during 1929 was 6*s.* 2*d.* as compared with 6*s.* 5*d.* in 1928.

Freight Train Traffic.—The total tonnage of goods and minerals conveyed (excluding companies free-hauled traffic) was 329,578,743 as compared with 306,128,804, tons in 1928.

The total tonnage and net ton-miles of freight traffic (including live stock and companies free-hauled traffic on standard gauge railways) increased by 7·02 and 6·31 per cent., respectively, compared with the year 1928.

On standard gauge railways the average lengths of haul were for general merchandise 91·15 miles, for coal, coke, and patent fuel 42·61 miles, and for other minerals 55·49 miles, in 1929, compared with 89·47 miles, 43·05 miles, and 54·36 miles respectively in 1928. For all descriptions of traffic the average haul was 53·69 miles, compared with 54·05 miles in 1928. The net tonnage miles per route-mile were 933,921, compared with 878,659, and the net ton-miles per engine-hour 446·65, compared with 438·16 in 1928.

The average receipts per freight train-mile from all freight were 14*s.* 10*d.* during 1929, as in 1928.

The average receipts per ton-mile on standard gauge railways were 2·269*d.* for general merchandise, 1·044*d.* for coal, coke, and patent fuel, and 1·105*d.* for other minerals in 1929, compared with 2·346*d.*, 1·059*d.*, and 1·123*d.* respectively in 1928.

Electrical Working of Railways.

The total length of road over which electrical trains were run increased from 560 miles in 1928, to 586 miles in 1929.

The car or wagon miles for passenger and freight services for 1929 compared with 1928 were as under :—

Service.	Car or Wagon Miles.	
	1928.	1929.
Passenger	251,219,260	273,848,467
Freight	3,201,992	4,278,389

(Sloson Thompson.)

Census of Staff.—The total number of persons employed by the railway companies in Great Britain (including the Railway Clearing House, but excluding the Manchester Ship Canal Co.) during the week ending 10th March, 1928, was 677,148, compared with 683,077 during the week ended 30th April, 1927.

Canals.—The tonnage originating on railway-owned canals in Great Britain in 1928 was 1,863,152 tons, as compared with 1,987,799 tons in 1928. Traffic originating on canals, other than railway-owned, in 1928, amounted to 12,710,685 tons, as compared with 13,185,072 tons in 1927.

Ministry of Transport Regulations with Reference to Railways.

See 'Requirements for Passenger Lines and Recommendations for Goods Lines of the Ministry of Transport in regard to Railway Construction and Operation.' H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2. Price 3*s.* net.)

Cost of Renewal of Railway Tracks.

At the Railway Rates Tribunal (1925) it was stated that on the Great Western Railway it was the general practice to renew the track on the main and principal lines with new materials; the serviceable materials recovered were used on secondary and branch lines. The mileage of the G.W.R. system which must be renewed with new materials was 4,194. The cost worked out at 3,000*l.* per mile. In 1913 the total mileage maintained was 6,709, and this was increased in 1924 to 6,915.

STANDING ORDERS OF THE HOUSE OF COMMONS WITH REFERENCE TO RAILWAY BILLS.

The following are the principal Orders relating directly to railways.

Estimate.

37. The estimate for any works proposed to be authorised by any railway, tramway, tramroad, subway, canal, dock, or harbour Bill shall be in the following form, or as near thereto as circumstances may permit :—

ESTIMATE of the proposed (Railway).

Line, No. . Whether Single or Double.

Length of line . . . . . *Miles. Fgs. Chs.*

Earthworks :	*Cubic Yds.*	*Price per Yd.*	£ *s. d.*	£ *s. d.*
Cuttings—Rock

Contingencies		per cent.		
Land and buildings : A. R. P.				
		TOTAL	£	

The same details for each branch, and general summary of total cost.

Plans.

42. In all cases where it is proposed to make, vary, extend, or enlarge any railway, the plan shall exhibit thereon the distances in miles and furlongs from one of the termini; and a memorandum of the radius of every curve not exceeding one mile in length shall be noted on the plan in furlongs and chains; and where tunnelling as a substitute for open cutting is intended, the same shall be marked by a dotted line on the plan, and no work shall be shown as tunnelling in the making of which it will be necessary to cut through or remove the surface soil.

43. If it be intended to divert, widen, or narrow any public carriage-road, navigable river, canal, or railway, the course of such diversion and the extent of such widening or narrowing shall be marked upon the plan; and if it be intended to divert any public foot-path, the course of such diversion shall be marked upon the plan.

44. When a railway is intended to form a junction with an existing or authorised line of railway, the course of such existing or authorised line of railway shall be shown on the deposited plan for a distance of 800 yards on either side of the proposed junction, on the same scale as the scale of the general plan.

Sections.

47. The section shall be drawn to the same horizontal scale as the plan, and to a vertical scale of not less than one inch to every one hundred feet, and shall show the surface of the ground marked on the plan, the intended level of the proposed work, the height of every embankment and the depth of every cutting, and a datum horizontal line, which shall be the same throughout the whole length of the work, or any branch thereof respectively, and shall be referred to some fixed point (stated in writing on the section), near some portion of such work, and in the case of a canal, cut, navigation, public carriage-road or railway, near either of the termini, the distance of such fixed point above or below an ordnance bench mark in the locality of the proposed works, and near one of the termini, and the height of such bench mark above ordnance datum shall also be stated.

48. In cases of Bills for improving the navigation of any river, there shall be a section which shall specify the levels of both banks of such river; and where any alteration is intended to be made therein, it shall describe the same by feet and inches, or decimal parts of a foot.

49. In every section of a railway the line of the railway marked thereon shall correspond with the upper surface of the rails.

50. Distances on the datum line shall be marked in miles and furlongs, to correspond with those on the plan; a vertical measure from the datum line to the line of the railway shall be marked in feet and inches, or decimal parts of a foot, at the commencement and termination of the railway, and at each change of the gradient or inclination thereof; and the proportion or rate of inclination between every two consecutive vertical measures shall also be marked.

51. Wherever the line of the railway is intended to cross any public carriage-road, navigable river, canal, or railway, the height of the railway over or depth under the surface thereof and the height and span of every arch of all bridges and viaducts by which the railway will be carried over the same, shall be marked in figures at every crossing thereof; and where the railway will be carried across any such public carriage-road or railway, on the level thereof, such crossing shall be so described on the section; and it shall also be stated if such level will be unaltered.

52. If any alteration be intended in the water level of any canal, or in the level or rate of inclination of any public carriage-road or railway which will be crossed by the line of railway, then the same shall be stated on the section, and each alteration shall be numbered; and cross-sections, in reference to the numbers, on a horizontal scale of not less than one inch to every three hundred and thirty feet, and on a vertical scale of not less than one inch to every forty feet, shall be added, which shall show the present surface of such road, canal, or railway, and the intended surface thereof when altered; and the greatest of the present and intended rates of inclination of the portion of such road or railway intended to be altered shall also be marked in figures thereon; and where any public carriage-road is crossed on the level a cross-section of such road shall also be added, and all such cross-sections shall extend for two hundred yards on each side of the centre line of the railway.

53. Wherever the extreme height of any embankment, or the extreme depth of any cutting, shall exceed five feet, the extreme height over or depth under the surface of the ground shall be marked in figures upon the section; and if any bridge or viaduct of more than three arches shall intervene in any embankment, or if any tunnel shall intervene in any cutting, the extreme height or depth shall be marked in figures on each of the parts into which such embankment or cutting shall be divided by such bridge, viaduct, or tunnel.

54. Where tunnelling as a substitute for open cutting, or a viaduct as a substitute for solid embankment, is intended, the same shall be marked on the section, and no work shall be shown as tunnelling in the making of which it will be necessary to cut through or remove the surface soil.

55. When a railway is intended to form a junction with an existing or authorised line of railway, the gradient of such existing or authorised line of railway shall be shown on the deposited section, and in connection therewith, and on the same scale as the general section, for a distance of 800 yards, on each side of the point of junction.

ELECTRIC TRACTION

ELECTRIC TRACTION ON LONG-DISTANCE RAILWAYS—ELECTRIC LOCOMOTIVES — LOCOMOTIVE BRAKES — SUBURBAN RAILWAYS — MOTOR-COACH CONTROL EQUIPMENT — TRAMWAYS — RAILS — TRACTIVE RESISTANCE — TRAMWAY MOTOR CONTROL — BRAKES — ELECTRIC EQUIPMENT OF TRAMWAYS — TROLLEYS — OVERHEAD CONSTRUCTION—POLES—TROLLEY WIRE — RAIL BONDING — CABLES — MINISTRY OF TRANSPORT REGULATIONS—SPECIFICATIONS—RAILLESS ELECTRIC TRACTION—BATTERY VEHICLES.

(Revised and Amplified by Prof. S. Parker Smith, D.Sc., Assoc.M.Inst.C.E., M.I.E.E.)

ELECTRIC TRACTION ON LONG-DISTANCE RAILWAYS.

There are at present four systems for electric traction on long-distance railways: (1) Direct-current, (2) Three-phase, (3) Single-phase, and (4) Split-phase—a combination of (2) and (3). The Three-phase system, although a complete success, has made considerable headway in but one country—Italy; its drawback is the double overhead conductor. The Direct-current, Single-phase, and Split-phase systems only are in active conflict to-day.

In most European countries the choice of system has been definitely decided by national commissions: these bodies, after weighing the facts, have set forth the details of the system most suited to their needs. Thus, in Great Britain the well-known report of the Electrification of Railways Advisory Committee has recommended the adoption of Direct-current at 1,500 volts. The same conclusion has been reached by the authorities in Holland, Belgium, Czecho-Slovakia, and France; whereas Switzerland, Germany, Austria, Sweden, and Norway have standardised the Single-phase system at low frequency. In the U.S.A. the electrification of the Chicago, Milwaukee, and St. Paul Railway, a large trans-continental route, on the Direct-current system at the high pressure of 3,000 volts, has had a considerable influence on some European decisions. The more recent adoption by the Virginia Railroad of the Split-phase arrangement for one of the heaviest freight services in the world has, however, again drawn attention to the capabilities of A.C. for electric train-haulage, while the Pennsylvania Railroad has adopted single-phase for a main line with heavy traffic.

The motors employed for Direct-current traction are universally of the Series type, yielding a torque which is greatest at starting, falling off as the speed rises. (See Section XXXV.) *Speed regulation*—a very important matter for locomotive work—is obtained by series-parallel grouping of the motors—the standard method employed in traction to vary the motor terminal voltage. Further speeds entail weakening of the motor field flux: a method, while economical, resulting in the reduction of the useful torque per ampere of armature current. Starting is effected by the insertion of resistance in the motor circuit. For passenger and express work the

losses in the rheostats may well be insignificant, but for goods and shunting operation, or where stops are frequent, these losses may become important.

For Single-phase traction in Europe, the Single-phase neutralised series motor is used almost universally; this machine is similar in principle and performance to its D.C. prototype, but has some inherent defects; these have now been overcome by sound design, although compromise and cost have figured largely in the solution, which involves the adoption of a low frequency ($\frac{50}{3} = 16\frac{2}{3}$ periods). The decisive advantage, however, is the feasibility of a high pressure on the contact line: 20,000 volts has been successfully tried, and 16,000 volts is standard practice. The stationary transformer is largely responsible for the success of Single-phase traction, both in its capacity of voltage transformation and of providing simple speed-regulation for the motors. No series resistance is required in the armature circuit, as the motor can be switched on to various tappings on the secondary side of the main transformer. This is of especial value for goods locomotives; while, in addition, starting can be economically graded to take up the slack in the wagon couplings.

In America the later developments in Single-phase train-haulage have been with the Split-phase arrangement. Here a higher frequency can be used on the lines with advantage. The high-voltage Single-phase energy taken from the trolley wire is transformed down on the locomotives and passed through a phase-converter, which supplies two- or three-phase energy to the induction motors used for traction. The use of these robust and efficient motors is a great advantage, and commutators are avoided. This is important in the U.S.A., where 25 cycles has become the standard frequency for A.C. traction. Polyphase induction motors are lighter than either D.C. or Single-phase machines, but speed regulation is difficult, complex pole-changing and cascading devices being required. Rheostatic starting is essential. The recuperation of energy by the motors when descending a grade is automatic, and this explains the adoption of the Split-phase system on lines dealing with heavy mineral trains on steep gradients; moreover, braking is positive; energy is returned to the line; tyres, brake blocks, and rails are subjected to less wear; and the high line-voltage makes the collection of large quantities of energy a simple matter. More recently the Single-phase-D.C. converter locomotive has been developed.

The straight Three-phase system possesses the disadvantage of requiring two overhead conductors, the track forming the third phase. The result is that the voltage between phases is limited, and the load is always more or less unbalanced. Even here, however, modern developments have improved the conditions, and the phase voltage has, experimentally, been trebled. Induction motors are used as for the Split-phase system, and three or four speeds are becoming common practice.

The systems employed for electric traction which have proved to be technically sound are shown in the following table, which traces the connection from locomotive to power-station:—

Equipment of			Supply.
Locomotive.	Track.	Substation.	
D.C. motor	Overhead wire Third rail	Rotary converter Motor generator Mercury rectifier and transformer	
Polyphase induction motor	Two overhead wires	Transformer	Three-phase at normal or low frequency.
Polyphase induction motor, with phase converter	Overhead wire	Transformer	
Single-phase series motor and transformer	Overhead wire	Motor generator and transformer Transformer	Single-phase at low frequency.

The choice of an electrification system in any specified case is first and foremost a matter of finance. In the main, the installation which is cheapest when taken from every standpoint is the system to be installed. An important secondary matter is interference with communication circuits. The following table will give some idea of the comparative advantages of the several systems:—

Item.	D.C.	Three-phase.	Single-phase.
Locomotives—			
Speed regulation	fair	worst	best
Starting economy	poor	poor	good
Motor transformer	none	optional	essential
Power factor	unity	good	fair
Efficiency	good	best	lowest
Recuperation of energy	fair	simple	fair
Current collection	worst	medium	best
Weight	heavy	light	heavy
Cost	medium	cheapest	dearest
Substations and Track Equipment—			
Contact line	good	complex	best
Interference (telephonic)	may be bad	may be bad	safeguards essential
Number and size of substations	largest	medium	smallest
Cost	greatest	small	lowest
Transmission lines—			
Cost	high	high	low
Power Stations—			
Generators	cheapest	cheapest	dearest
Overall cost	least	least	most
Complete Installation—			
Overall efficiency	47–61 per cent.	45 per cent.	50–68 per cent.
Overall cost	not much difference		

The following summary shows the chief developments in Long-distance and Main-line electric traction. Unless otherwise indicated the lines are now running electrically.*

Austria.—The decision on July 23, 1920, by the National Assembly to electrify 650 km. of route was influenced by the urgent need of reduction in the consumption of imported coal and utilisation of available water-power resources to assist in restoring economic independence. The system of electrification has been under consideration for many years, and the commission formed for that purpose has decided to adopt the Single-phase system at 15,000 volts, $16\frac{2}{3}$ periods. The chief lines running or under construction, together with some privately owned lines, are noted in the table below :—

Railway.	Section.	Route Length. Km.	System.	Remarks.
Austrian Federal Railways	Innsbruck–Lindau	235	Single-phase, 15,000 volts, $16\frac{2}{3}$ periods.	Mountain line.
	Salzburg–Worgl	192		Heavy traffic.
	Schwarzach–Villach*	117		Mountain line.
	Stainach–Attnang	107		—
Mittenwald	Innsbruck–Reutte	105	Single-phase, 15,000 volts, $16\frac{2}{3}$ periods.	Connects Tyrol–Bavaria.
Lower Austrian Railways	Vienna–Pressburg	68	Single-phase, 15,000 volts, $16\frac{2}{3}$ periods.	D.C. in Vienna and Pressburg.
	St. Polten–Mariazell	91	Single-phase, 6,600 volts, 25 periods.	Tourist traffic.

The present work on the Federal Railways was due for completion in 1925, after which a further group, totalling 1,135 km., was to have been converted: financial difficulties have delayed progress. Cheap coal may also retard development.

* An asterisk denotes lines at present under construction.

France.—Although the coal situation in France is not so critical as in some other parts of Europe, it is nevertheless serious. The question of main-line railway electrification has been much to the fore since 1918, when a commission investigated existing railways in Switzerland, Italy, England, and the U.S.A. The operation of the Chicago, Milwaukee, and St. Paul Railway, in the Western States of the Union, was closely studied, and a report was made in favour of the D.C. system, but at 1,500 volts. Three of the French railway companies, as detailed below, have embarked on large electrification schemes. Supply will be obtained solely from hydro-electric stations, except in the case of the Paris–Orleans line, for which a supply will also be taken from parallel-working steam stations near Paris.

Railway.	Section.	Route Length. Km.	System.	Remarks.
Paris–Orleans .	Paris–Vierzon .	916	D.C., 1,500 volts	Heavy traffic—partly completed.
	Vierzon–Brive* .			Mountain lines.
	St. Sulpice–Gannat*			
	Brive–Clermont*			
Paris–Lyons–Mediterranean .	Culoz–Modane* .	149	D.C., 1,500 volts	Mountain line.
	Nice local lines* .	174		Suburban.
Midi . .	Bordeaux–Toulouse and branches. Part now working.	1,782	D.C., 1,500 volts	Main line connecting with mountain branch lines, partly converted from one-phase system.

As it is still an open question whether the overhead wire or the third rail should be used, locomotives, etc., are being provided with two types of collecting gear.

Germany.—Electrification on a large scale had already begun in Germany previous to the war, and several experimental tracks had been equipped. The Leipzig–Magdeburg line, in the plains of the Elbe, the Silesian Mountain Railway, the Wiesenthal Railway, in Baden, and some of the South Bavarian lines were already electrified. After 1918 it was realised that the natural resources of the country had to be conserved. For districts lacking in water-power, large steam-stations capable of using inferior lignite coal were proposed. For Bavaria, an extensive scheme is being carried out, the electric power network being fed from hydro-electric stations at Walchensee and on the Middle Isar River: a separate supply network will feed the railways. The question of system was investigated both before and after the war, and in the report of December 1921 it was unanimously decided that the system best suited to the governing conditions was the Single-phase at 15,000 volts, $16\frac{2}{3}$ cycles, with a separate supply for the railways.

Railway.	Section.	Route Length. Km.	System.	Remarks.
German Federal Railways .	Silesian Mountain Rly.	259	Single-phase, 15,000 volts, $16\frac{2}{3}$ periods.	Mountain lines.
	Magdeburg–Leipzig .	177		Heavy traffic.
	Bavarian lines* .	672		Hydro-electric supply.
	Wiesenthal Railway† .	49		

Electrification is sufficiently far advanced in Germany to enable a decision to be reached as to rolling-stock standardisation, and the administration have standardised six locomotive types to suit all the conditions met with.

Great Britain.—Great Britain has comparatively little to show in the way of long-distance railway electrification, although there are numerous schemes and projects under consideration.

Standards for British Railway Electrification.—An attempt has been made to standardise the system, etc., for future developments, but a certain amount of latitude has been allowed, as the following will show:—

The Electrification of Railways Advisory Committee, appointed by the Minister of Transport in March 1920, issued its final report in September 1921, recommending that all new electrification

* An asterisk denotes lines at present under construction.
† 15 periods.

should be on the direct-current system, and that the standard pressure should be 1,500 volts, except in the case of railways already operating at 600 or 1,200 volts D.C., or with alternating current. The adoption of 750 or 3,000 volts should be permitted where approved by the Minister. Both overhead and rail conductor collection were recommended, provided that the form and design of the conductors and structures were in accordance with specified regulations. Current should be generated on the three-phase system, at the frequency in general use in the district concerned; 50 cycles could be used satisfactorily. Suggested regulations were given, with drawings, for the standardisation of contact rails.

The Railway Electrification Committee (1927) reviewed the 1921 recommendations in a report issued in 1928. It was found that extensions had been made to existing lines at 600 and 650 volts, making a total of 1,404 miles of track at low-voltage D.C., 77 miles of 1,500-volt D.C., and 19 miles of Single-phase, the Brighton section of the Southern Rly. having been converted to D.C. The Committee therefore recommended the adoption of D.C. working at 'maximum' standards of 750 and 1,500 volts, with third rail and overhead contact systems respectively, and with generation at 50 cycles, 3-phase. The Committee did not consider it necessary to provide for the inter-running of multiple-unit rolling stock between high- and low-voltage electrified sections. For locomotives, however, to enable inter-running to be effected, two maximum loading gauges were prepared. No. 1, with a maximum height of 12 ft. 8 ins. above rail level, will be suitable for inter-running on all British railways, except on certain short lines, such as light railways, tube lines, and goods branches, totalling 264 miles. Such locomotives will have a scope of practically the whole of the 20,000 route miles of railway. No. 2 takes advantage of the higher (13 ft. 2 ins.) loading gauges of the L.M. & S., L. & N.E., G.W., and Southern (central section main line) Railways, and locomotives constructed to this gauge will have a scope of rather more than 13,000 miles. A suitable overhead-contact current collector was suggested. To permit of inter-running electrically, locomotives should be equipped with 750-volt motors capable of being connected in series-pairs for operation on 1,500 volts, and both overhead and shoe collectors should be provided. The reservation was made that the electrical standardisation need not be effected by a railway company until one-third of its total locomotive stock has been replaced by electric engines. Details of third rail and overhead clearances were specified. The Committee considered it undesirable to set limits to the voltage drop and uninsulated return conductors, a decision with which representatives of the G.P.O. were in disagreement.

A further Government inquiry into main-line electrification was instituted in 1929.

Holland.—In consequence of the recent decision of the Dutch commission on the subject the future development of electric traction will be on the high-voltage D.C. system. The railways will be fed from a unified network of steam power-stations, and it is considered that for this purpose D.C. offers the most decided advantages. At the same time, the only long-distance line at present in operation is the Rotterdam–Scheveningen Railway, which employs single-phase energy at 10,000 volts, 25 cycles. The line intended for the first step in future D.C. electrification is the Rotterdam–Haarlem–Amsterdam railway.

Railway.	Section.	Route Length. Km.	System.	Remarks.
Dutch State	Rotterdam–Scheveningen	36	Single-phase, 1,000 volts, 25 periods.	Semi-suburban traffic.
	Rotterdam – Haarlem–Amsterdam* . .	—	D.C., 1,500 volts.	Main route.

Hungary.—The rearrangement of the international boundaries after the war lost to Hungary her complete oil and natural gas resources, two-thirds of her coal-fields, and nearly the whole of her water-power. The railways must, therefore, be electrified, in order to reduce imports, to conserve what coal and peat remain, and because the available fuel is only suitable for power-station combustion. While plans are ready for the eventual conversion of 1,385 km. of route, only a short 15-km. line has at present been equipped between Budapest and Dunakeszi–Alag. The system proposed is the split-phase arrangement with 15,000 volts, 50 periods on the track, in order to supply the line from phases of the industrial network, and tests under these conditions have proved satisfactory.

Italy.—The electrification of the Italian railways dates back to the beginning of the present century, and provides practically the earliest example of main-line electrification in Europe. This fact largely explains the adoption of the three-phase system at 3,000 volts, 15 periods, at

* An asterisk denotes lines at present under construction.

the outset, for at the time the high-voltage D.C. and Single-phase systems were in their infancy. Although it seems likely that Italy will adhere to the three-phase system, yet there are indications that the line voltage will be raised to 10,000 volts, and the frequency to that commonly met with in the surrounding industrial districts. The reasons for electrification here, as elsewhere, were economical, owing to lack of coal and the existence of abundance (in some districts) of water-power. The Valtellina line in Northern Italy was the first electrified, and other lines have been added from time to time, until now about 670 km. of route is in operation, while very extensive programmes exist for future developments. High-voltage D.C. traction is being tried in the south.

Railway.	Section.	Route Length. Km.	System.	Remarks.
Italian State Railways	Milan–Varese	73	D.C., 650 volts.	Third rail : date 1901.
	Valtellina lines	143		First 3-phase line.
	Giovi lines Savona–Sampierdarena Savona–Ceva Alessandria–Voghera Novi-Tortona–Ronco	241	Three-phase, 3,000–3,700 volts, 15–17 periods.	Among the most heavily worked lines in Italy. Steep gradients and long tunnels.
	Mt. Cenis line	113		Through Mt. Cenis Tunnel.
	Turin lines	173		
	Rome–Tivoli	40	Three-phase, 10,000 volts, 45 periods.	Industrial frequency.
	Benevento–Foggia	—	D.C., 3,000 volts.	Experimental.

Scandinavia.—In Sweden the question of main-line railway electrification has been discussed since 1899. In 1915 the first section of the Riksgransen Railway was put into operation. This line carries heavy mineral trains from the iron-ore mines of Kiruna and Gellivare to the coast at Narvik and Lulea. The line is run at 16,000 volts, single-phase, 15 cycles, under the most severe climatic conditions. Since 1918 the Swedish State Railways Electrification Commission have considered afresh the question of system, and the choice of Single-phase has been confirmed. The Norwegian authorities have come to a like decision. The Swedish Stockholm–Gothenburg line is in process of conversion to electric traction : this line will be fed from the three-phase industrial network through converter stations at 15,000 volts, $16\frac{2}{3}$ cycles. The Norwegian developments comprise the completion of the Riksgransen Railway to Narvik and the equipping of the Kristiania–Drammen Railway.

Railway.	Section.	Route Length. Km.	System.	Remarks.
Swedish State Railways	Narvik–Riksgransen–Lulea*	472	Single-phase, 16,000 volts, 15 periods.	Mineral line.
	Stockholm–Gothenburg	458	Single-phase, 15,000 volts, $16\frac{2}{3}$ periods.	Main line traffic.
Norwegian State Railways	Kristiania-Drammen	53	Single-phase, 15,000 volts, $16\frac{2}{3}$ periods.	Semi-suburban.

Switzerland.—The need for national independence by utilising water-power instead of importing coal has long been recognised. While a few local railways are operated with D.C., and two important lines with three-phase, the main bulk of the electrified railways use the Single-phase system, at $16\frac{2}{3}$ cycles, which, after a protracted study, was recommended by the Administration of Railways in 1912. The single-phase lines comprise the Federal Railways, the Loetschberg Railway, and the metre-gauge Rhaetian Railways. The latter are operated at

* The Narvik–Riksgransen part is in Norway.

11,000 volts, and the others at 15,000 volts. All the power is obtained from hydro-electric stations fed from rivers or lakes in such a way that the supply is maintained reasonably constant all the year round. All the Federal main lines have been electrified, and the Simplon line changed to single-phase.

Railway.	Section.	Route Length. Km.	System.	Remarks.
Loetschberg and Bernese Subsidised Railways	Berne–Thun–Brieg and branches	194	Single-phase, 15,000 volts, $16\frac{2}{3}$ periods.	International through route.
Rhaetian Railways	Chur–Landquart–Klosters–Filisur, etc.	277	Single-phase, 11,000 volts, $16\frac{2}{3}$ periods.	Metre-gauge.
Swiss Federal Railways	St. Gothard line, Rhone Valley, etc.	1645	Single-phase, 15,000 volts, $16\frac{2}{3}$ periods.	International routes.
	Simplon Tunnel	22		Continuation of Loetschberg and Rhone Valley lines.

United States of America.—Largely on account of its immense size and development, most of the important and extensive railway electrification projects are to be found in the United States.

Chicago, Milwaukee, and St. Paul Rly.—At present the C.M.S.P. Railway is the largest electrified line in the world as far as route length is concerned. It is a trans-continental road, operating electrically the single line over the Rocky Mountains, with very heavy trains on long gradients. The system employed is the direct-current at 3,000 volts on the contact line. On the down-grades regenerative braking is extensively used—on the whole, quite successfully. Both geared and gearless types of locomotive are employed.

Butte, Anaconda, and Pacific R.R.—This road is engaged principally in the haulage of copper ore by locomotives, on the 2,400-volt direct-current system. It was the original example of high-voltage D.C. applied to heavy railway operation, and served as a model for the C.M.S.P. Railway.

New York Central R.R.—The electrified portion comprises a 30-mile zone in the Hudson River and Haarlem Divisions, both locomotives and multiple-unit trains being employed. The system is D.C., 650 volts, with third rail.

New York, New Haven, and Hartford R.R.—A great deal of pioneer work has been done by this company, which now operates an 11,000-volt network running out to New Haven. The trains, hauled by locomotives or motor-coaches, run into New York over the N.Y.C. tracks (D.C., 650 volts), with the result that the equipment in many cases is very complicated.

Pennsylvania R.R.—For some years the New York terminus has been electrified at 650 volts D.C., and branch lines round Philadelphia at 11,000 volts, 25 cycles. The electrification is now in progress of the main line between New York and Wilmington, Delaware, on the single-phase system at 11,000 volts, 25 cycles.

Norfolk and Western Rly.—Mineral traffic of a very heavy character is hauled on this line. The locomotives are of the split-phase type, taking single-phase energy from the contact line at 11,000 volts, 25 periods, and supplying three-phase induction motors through a phase converter: the ease with which regenerative braking is effected is a very noticeable feature.

Great Northern Rly.—The new 8-mile Cascade Tunnel was opened in 1928, and is worked at 11,000 volts, 25 cycles. With approaches, the electrified zone is 75 miles.

Virginia R.R.—A recent contract of 15 million dollars has provided for the electrification of the Va. R.R. between Mullens and Roanoke, over a mountainous route of 135 miles. At present, with steam haulage, the company is moving 7 million tons of coal per annum, and the limit has been reached. Electrification (single-phase, 11,000 volts 25 cycles) will enable 6,000-ton

trains to be hauled up the 2 per cent. grades at 14 m.p.h. The locomotive units will weigh 200 tons each, and will provide, when coupled in sufficient numbers, 12,000 h.p. The regenerative braking of the split-phase system to be installed is of paramount importance.

Detroit, Toledo, and Ironton R.R.—This railway, in which Mr. Henry Ford has the controlling interest, has a length of route under conversion to electric traction. A 22,000-volt, 25-cycle, single-phase, contact-line pressure will be used. The locomotives will carry transformers and motor-generators for supplying normal D.C. series traction motors.

Other initiated or completed lines include Reading Co.; Boston, Revere Beach and Lynn R.R.; Delaware, Lackawana, and Western R.R.; Cleveland Union Terminal Co.; and Illinois Central.

Railway.	Section.	Route Length. Miles.	System.	Remarks.
Chicago, Milwaukee, and St. Paul Rly.	Harlowton–Avery Avery–Othello* Othello–Seattle	874	D.C., 3,000 volts	Transcontinental.
Butte, Anaconda, and Pacific R.R.	Butte–Anaconda	25	D.C., 2,400 volts	Mineral line.
New York Central R.R.	Hudson River and Haarlem division	58	D.C., 650 volts	Heavy suburban.
Pennsylvania R.R. (New York)	New York Terminal and Long Is. R.R.	103	D.C., 650 volts	Extensive suburban.
New York, New Haven, & Hartford R.R.	New York – New Haven, etc.	88	Single-phase, 11,000 volts, 25 periods.	Suburban and main line traffic.
Norfolk and Western Rly.	Bluefield–Vivian	29		Heavy coal trains.
Pennsylvania R.R.	Philadelphia–Paoli	30		Suburban.
" "	NewYork–Wilmington	—		Main-line traffic.
Virginia R.R.	Mullens–Roanoke	135		Record train weights.
Gt. Northern R.	Cascade Tunnel	75		8-mile tunnel.

Other Developments.—In many other countries the railway electrification movement has begun. In Morocco a 416-km. line is to be electrified at 3,000 volts, D.C.: motor-coaches will work at this pressure. In New Zealand, the Arthur's Pass section of the Government Railways was opened on August 6, 1923, using the 1,500-volt D.C. overhead system. Important installations have been completed, or are under construction, in Brazil (Paulista Railway, 28 miles, 3,000 volts D.C.); Chile (Bethlehem–Chile Railway, 15 miles, 2,400 volts D.C.); Japan (Tokio–Yokohama–Kozu, 65 km., 1,500 volts D.C.); and in South Africa (Glencoe–Pietermaritzburg, 3,000 volts D.C.); Java (Tanjong Priok harbour–Weltevreden, 16 km., 1,500 volts D.C.); Spain (Northern Rly., Pajores gradient, 40 miles, 3,000 volts D.C.).

Electric Locomotives.

The first electric locomotives were developed directly from the street tramway, and had bogie tracks provided with nose-suspended motors. Progress in America has in general avoided mechanisms involving reciprocating motion, and the nose-suspension and the quill drives have been widely applied to passenger, freight and shunting locomotives. On the Continent of Europe there was a widespread tendency at first to apply the steam locomotive side-rod mechanism to the electric locomotive. Many difficulties were encountered and generally overcome, but the continuous torque of the electric motor was fundamentally unsuited to the reciprocating nature of the drive, whilst the effect of steam cushioning in the steam locomotive cylinders had no counterpart in the electric drive. Subsequent designs introduced springs and similar elastic members to provide for this, and to obviate the troublesome oscillatory phenomena in side-rod drives so damaging to the bearings. The present tendency in Europe is to return to individual-axle drives with nose-suspended motors or with some form of special gearing enabling the motors to be entirely spring-borne. Among these are the Westinghouse (geared-quill, with spring connection between gear wheel and driving wheel) and the Buchli (link connection) drives, and a later form of bevel drive in which the motors have vertical shafts. Individual-axle drives allow greater freedom in the running-gear design and are adaptable to most classes of service, tending to simplification of spare parts and maintenance. The locomotives built in Great Britain have been mostly fitted with nose-suspension drives. Various types of contactor control are used.

FIG. 1.

Brakes for Electric Locomotives.

(The Consolidated Brake and Engineering Co., Ltd.)

The diagram (fig. 1) shows a brake equipment for electric passenger locomotives for heavy duty on steep grades, operating vacuum-braked trains, the locomotives being fitted with an air-pressure brake.

To synchronise the brakes on the locomotive and the train and also to give proportionate control, a combination brake-control valve is provided. This valve is governed by the vacuum in the continuous train pipe of the vacuum brake and directly admits a corresponding air pressure to pass to the air-brake cylinders upon the locomotive, giving a perfectly synchronised and balanced braking effect throughout the train and avoiding bunching at the forward end, and shocks.

The air brake can be used independently if desired, by use of the straight air-brake valve; this is useful in shunting operations. The vacuum brake can also be operated upon the train independently of the air brake, for which purpose a magnetic intercepting valve is provided.

The vacuum exhausters are of the rotary drum type directly coupled to the motors with a two-speed control. The full speed is for quickly releasing the brakes or charging up the system rapidly if time is limited. The slow speed is for maintaining vacuum and for brake control generally, the full speed only being used as circumstances require. The two speeds are suitably controlled by contacts on the spindle of the driver's vacuum brake valve, which allows slow speed in all positions except full release, in which position the exhausters run at full speed.

The motor-driven air compressors, in addition to providing compressed air for the locomotive brakes, also supply the necessary air for the sanding gear, pantograph operating apparatus, pneumatic control, and whistles.

ELECTRIC TRACTION ON SUBURBAN RAILWAYS.

Much of the electrification work hitherto has been in connection with suburban railways around large cities like London, New York, and Paris. Such lines form a most promising field for the utilisation of electric power, as they usually carry heavy and dense traffic, a condition very favourable to electric traction. Of course, on tube and similar underground railways anything but electric haulage in the light of modern requirements is unthinkable. For suburban and urban traffic the single-phase system is seldom considered unless some ulterior condition makes this advisable: in practically all cases the direct-current system is used, at voltages of 600 to 1,500, with third-rail collection. It is standard practice to generate three-phase energy in the power stations, transforming to suitable pressures for transmission to the substations. The motor-generators formerly used for A.C.-D.C. conversion are now displaced by the rotary converter, which has higher efficiency and overload capacity. The mercury vapour rectifier is also coming into use (See Section XXXV., Electrical Engineering.)

With the use of 600 volts (or more) for traction on lines of a suburban character, it is usual to replace the hand controller suitable for tramway operation by the multiple-unit control, which consists of small manual or automatic 'master-controllers' operating separate switches or 'contactors,' connected to the motors and to the tappings of the resistance grids. The contactors may be either electro-magnetically or electro-pneumatically operated. Electric coupling between the adjacent coaches permits the use of any one master-controller for the control of the train. The advantages of this so-called multiple-unit control lie in the flexibility of train length, the provision of a motor capacity always suitable to the load (for the maintenance of a uniformly fast service), and the efficient utilisation of the available adhesion (for rapid acceleration).

For leading the current to the moving trains a third rail is provided for each track, the motor coaches being equipped with cast-iron contact shoes for current collection. In England, where the Board of Trade regulations require a very small drop in the earth return, it has been necessary on occasion to add an insulated fourth rail in order to avoid the drop in the running rails which elsewhere serve as a return. This may often be of considerable advantage in cases where track-circuiting is required for automatic train-signalling. Fig. 2 illustrates a typical contact rail construction for a tube line.

On most city and suburban electrified railways dealing with heavy traffic, automatic signalling is employed; indeed for many of the congested services it is essential. Where a fourth-rail return is used, the running rails are used to convey direct or alternating current for the track circuits. Where, however, the running rails carry the power current, alternating current alone may be employed for signalling. For automatic signalling the reader should consult Section XIII., p. 645.

For lines with infrequent service the efficiency of the substations is comparatively low, while the running costs are high in consequence of the fact that the numerous substations must be capable of supplying the peak load. The transmission losses in the conductor rails are also considerable. In such cases automatic or semi-automatic substations, with higher line voltages, may be used.

Low-pressure traction motors are now standardised, as also is their control. Series-parallel arrangement of the motors of each bogie (of the motor coach) is universal practice. In special cases field-shunting is used, as, for instance, when trains make occasional runs to outlying districts. The diagram of tram-motor control given in fig. 4, p. 690, is typical also of motor coaches, except that switching operations, as already indicated, are performed by contactors operated from the master controller.

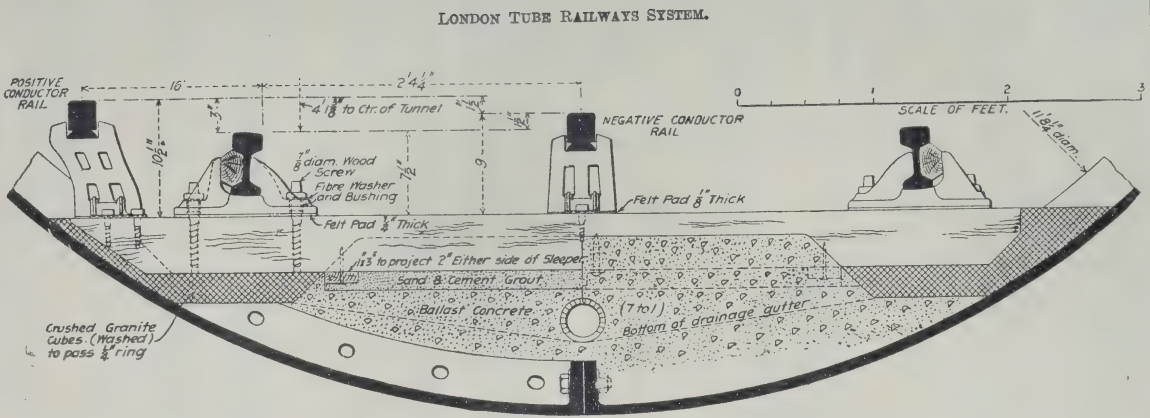

FIG. 2.—Type of Construction of Permanent Way and Conductor Rails on the tube lines of the underground railways of London.

Train units are usually made up of motor-coaches and trailer coaches. A common arrangement is one motor-coach semi-permanently coupled to one or more trailers. In such a case the end trailer is a driver trailer, and is provided with a driver's cabin with a master controller and the necessary apparatus for reversed operation. One, two, three, or more units may be coupled and controlled by one driver to form a train of any desired size according to traffic needs, and the same schedule may be maintained regardless of the train-length, since the power/weight ratio remains constant.

The following are brief details of some important suburban electrification systems:

London.—A large network of electrified lines exists in the south and west of London. The north-east district has hitherto been largely neglected. The Southern Railway has the largest suburban electrification in the world.

Line.	Route.	Route Length. Miles.	System.	Remarks.
Underground.	Metropolitan-District Rly.	28·5	D.C., 550–600 volts, third or third and fourth rail.	Surface and sub-surface.
	Bakerloo Rly.; Piccadilly Rly.; Edgware, Highgate & Morden Rly.; City Rly.	44		Deep-level tubes with surface extensions.
	Central London Rly.	11·1		
Metropolitan.	N. side of 'Inner Circle'; Harrow main line	29·5		Surface and sub-surface.
L.M. & S. Rly.	Euston and Broad St. to Kew, Watford, etc.	38·5		Surface, main-line terminus.
Southern Rly.	All sections . . .	173		Surface, main-line termini.

Paris.—The C. de F. Métropolitain and Nord-Sud operate sub-surface lines covering the area bounded by the old city walls. Stations are closely spaced, allowing of competitive services with street transport. The C. de F. de l'État (Ouest) works two suburban lines and a short local city branch to Auteuil Boulevard. The electrification of the C. de F. de Paris-Orléans embodies the main line out of Paris.

Line.	Route.	Route Length. Miles.	System.	Remarks.
Métropolitain.	Route Nos. I.–X.	62 *	D.C., 600 volts, third rail.	Sub-surface city lines.
Nord–Sud.	Clichy, St. Ouen, and la Chappelle to Porte de Versailles.	10 *	D.C., 700 volts, third rail and overhead line.	
État (Ouest).	Invalides–Versailles, St. Lazare–St. Germain, etc.	30 *	D.C., 750 volts, third rail.	More lines in process of electrification.
Paris–Orléans.	Quai d'Orsay–Juvisy, etc.	14·6	D.C., 1,500 volts, third rail and overhead line.	Part of extensive main-line electrification.

* Further lines projected.

Berlin.—The Hoch- und Untergrundbahn, serving city districts, was begun in 1902. The lines of the Reichsbahngesellschaft round Berlin, including the Stadt- und Ringbahn, are now being converted to electric haulage.

Line.	Route.	Route Length. Miles.	System.	Remarks.
Hoch- u. Untergrundbahn	City lines.	31·5	D.C., 800 volts, third rail.	Sub-surface and overhead.
Stadt-, Ring u. Vorortbahnen	Stettiner Bahnhof, Bernau, Oranienburg and Velten.	45·7 *		Extensive programme of electrification in hand.

* Further lines under conversion.

Melbourne and Sydney.—These two capital cities of Australia have modern electrification systems (complete or projected) of a very extensive nature, since far-seeing town planning has led to a wide distribution of suburban population.

Line.	Routes.	Route Length. Miles.	System.	Remarks.
Victoria Govt. Rlys.	Melbourne City and suburban lines.	154	D.C., 1,500 volts. overhead line.	
N.S. Wales Govt. Rlys.	Sydney Central – Sutherland.	23		Extensive scheme under conversion.

New York.—On account of its geographical peculiarities the city of New York has for many years been subject to traffic congestion in a north-south direction along the line of Manhattan Island. In addition, there is a heavy traffic movement east and west between Manhattan and Long Island (Brooklyn, Queens, etc.). The following are details of the principal lines:

Line.	Routes.	Route Length. Miles.	System.	Remarks.
Brooklyn Rapid Transit Co.	Manhattan–Brooklyn and Coney Island lines.	89·2	D.C., 600 volts, third rail.	Surface and elevated along main streets.
Hudson and Manhattan R.R.	Newark – Hoboken – South Manhattan.*	7·9		Surface and tunnel lines.
Interborough Rapid Transit Co.	Manhattan – Bronx and connection with B.R.T. Co.	114·7		Subway and elevated lines.

* Partly over Pennsylvania R.R. Co.'s tracks.

EQUIPMENT FOR MOTOR-COACH TRAINS.

Camshaft Control.

(The English Electric Co., Ltd.)

The main contactors in this system are operated by means of a camshaft under the control of a small pilot motor. The control circuits are operated at 120 volts, this supply being obtained from a motor generator set. The equipment includes the following essential features :—

(*a*) A camshaft composed of steel cams mounted on a mica-insulated steel shaft of square section. On rotating this shaft the cams close and open the main contactors in a definite predetermined sequence.

(*b*) A small pilot motor which drives the camshaft through suitable reduction gearing. This motor is controlled by the master controller and the position regulator, the latter being mounted on an extension to the camshaft itself.

(*c*) Two solenoid or cam-operated line breakers arranged in series to break the main circuit.

(*d*) All necessary auxiliary control gear, such as an electrically operated reverse, motor cut-out switch, overload relay, etc.

The closing of each contactor is effected against a strong spring by the rotation of the camshaft, so that the action is positive and the pressure constant, irrespective of the line voltage. Furthermore, the camshaft gives a definite mechanical interlock, controlling the sequence of operation of the contactors, and obviates the necessity for fitting electric interlocks. Since all current is broken on the line breakers, and the sequence of operation of all contactors is definite, the resistance contactors do not break any current, and are therefore not fitted with blowouts. The two contactors which deal with the operation of transition are called upon to break relatively small currents, and are fitted with blowouts. This arrangement effects a considerable reduction in the number of current-breaking contactors.

The line breakers are each fitted with a strong metallic blowout of the metallic shield type, and, in addition to their function of line breaker, are arranged to operate in conjunction with an overload relay as circuit breakers. Protection against dead short-circuits is given by special heavy duty-type cartridge fuses mounted on the roof of the motor coach. The fields of the pilot motor are separately and permanently excited at full strength from the 120 volts control circuit. The feed to the armature is taken through the camshaft motor relay, which is arranged to make this circuit when the coil is energised. Directly the coil becomes de-energised the clapper falls back, short-circuiting the armature of the pilot motor under full field, thus giving an absolutely dead beat check to the movement. The camshaft is returned to the off position by means of the pilot motor : this is effected by means of auxiliary contacts on the line breakers, which reverse the connections to the motor armature when the line breakers are in the open position. Thus, when the line breakers open, the camshaft is at once returned to the off position, and it is impossible for the motor to run in the forward direction so long as they remain open. A further interlock on the position regulator makes it impossible to reclose the line breakers until the camshaft has reached the off position. In the event of manual operation being used, the control of the notching up is, of course, entirely in the driver's hands. When automatic operation is used, the driver throws his control handle right round to the full parallel position, leaving the current limit relay to control the rate of notching up. The current limit relay is cam-operated. It is mounted on an extension to the camshaft itself and is, therefore, mechanically interlocked with the resistance contactors and position regulator.

Electro-magnetic and Electro-pneumatic Control.

In the electro-magnetic system the contactors for effecting the motor and rheostat combinations are controlled electrically from the master controller by means of magnet coils energised from the line (if the voltage be below 600 volts), or from a low (*e.g.* 32-volt) circuit, comprising a dynamotor or motor-generator or battery. Interlocking is effected by auxiliary contacts on each contactor. After being closed the control of the contactor is transfered from a 'closing' to a 'holding' coil demanding less energy. Each contactor may require several pairs of interlock contacts, according to the system or design adopted. The direction of rotation of the motors is controlled by a separate reverser. The electro-pneumatic system embodies electrically-controlled needle valves for compressed air cylinders operating the contactors mechanically. Later developments involve the use of individually-operated pneumatic contactors effecting the motor combinations, the rheostats being cut out by means of a drum-type controller operated by a differential air motor. These systems are lighter, cheaper, and less complicated for automatic control. Pneumatic control has the advantage that the control voltage is low ; a large mechanical force can be developed by a small and light compressed-air cylinder, and a spring relied upon for opening the contacts ; the mechanical operations are performed independently of the line voltage, avoiding the tendency of electro-magnetic contactors (fed from the line voltage) to vibrate and weld together when the line voltage falls to a low value.

Control of Alternating-Current Traction Motors.

The majority of single-phase motors are of the neutralised series type, and the basic method of speed control is the variation of the motor terminal voltage. Since a main transformer is invariably used, the methods available are: (*a*) Transformer tappings, controlled by contactor gear. To avoid interrupting the motor supply, a second tapping must be closed before the first is opened. The section of the transformer between the two tappings is protected by an auxiliary choking or 'preventive' coil. (*b*) Transformer tappings with sliding contact switch, developed by Brown, Boveri. The tappings are changed by means of a sliding contact switch driven by a screwed shaft operated by a control motor from the master controller. (*c*) Transformer tappings with induction regulator. This allows of fewer tappings, but owing to its greater complication has found only a restricted application. The advantage is the absence of jerky control.

Polyphase induction motors with slip-ring rotors are controlled by means of rotor rheostats (usually of the liquid type) combined with cascade connection. Motors with cage rotors are started with reduced voltage (by auto-transformer), combined with pole-changing connections.

The following details refer to typical motor-coach equipments with multiple unit control:

ELECTRIC TRACTION ON TRAMWAYS.

The technical arrangements for electric tramways are practically standardised all over the world. Two 4-pole totally-enclosed series motors are used, either with or without interpoles. The nominal rating of each motor is 30 to 50 h.p. with double-decked cars. The current transmission is effected by means of an overhead trolley-wire and rail return, collection being performed with a wheel trolley or sliding bow-collector. The voltage is most commonly 500 to 600, although a few American inter-urban roads have adopted a pressure of 1,200 volts. For control, a drum-controller is used, allowing of series-parallel and field-weakening methods for the regulation of the speed. Braking is by air or electric devices, the latter including rheostatic and magnetic track-brakes. Hand-controlled braking is used as a standby. On tramway systems where air-brakes are not used, the hand brakes are used for ordinary service stops and the electric only when going down steep hills or for emergency stops. For tramway substations, rotary converters have replaced the older motor-generator sets, but mercury-vapour rectifiers are coming into use for modern installations (see Section XXXV, Electrical Engineering).

Tramway Tyres and Axles.

The British Engineering Standards Association has issued standard specifications Nos. 101—1929 for tramway tyres and 102—1930 for axles. The former includes particulars of the tests to be applied, and a drawing showing the shape and dimensions of the tyre of standard section. The latter specifies that the steel shall not contain more than 0·05 per cent. of sulphur or phosphorus, and defines the tests to which the axle shall be subjected.

New tyres should be turned to the same angle of inclination as the worn head of the tramway rails has assumed, and care should be taken to ensure that the tyres fixed on the same axle should be of equal hardness, in order to ensure the maintenance of equal diameters in service.

Tramway Rails.

In Great Britain the grooved girder rail is practically the only type employed for tramways constructed in public roadways.

On some inter-urban tramways, with tracks laid on private lands, ' tee ' section rails have been used, loose guard-pieces being bolted on at curves; on single lines, having passing places with automatically worked points, ' tee ' rails present practical difficulties, and the later tendency is to use a special type of the ordinary grooved girder rail for such lines.

Twenty to thirty per cent. more power is required to run cars on a grooved rail than on a ' tee' rail, due to side friction, dirt in grooves, &c.

When gauge is 4 ft. or less, in order to allow room for removing motors, special rails, without overhang, should be fixed at car pits.

Weight of straight-track rails used in this country varies from 65 lbs. per yard, as at Coventry and Norwich, to 108½ lbs. per yard, as at Sheffield, Leeds, Wigan, &c. Rails of from 90 to 105 lbs. per yard are now generally adopted, with depth from 6 ins. to 7 ins., and width of base 6½ ins. to 7½ ins. The rail now used in Glasgow is ' B.S.' section No. 8, the weight being 112·9 lbs. per yard. No. 8c, weighing 119·2 lbs. per yard, is used at curves. The depth is 7 ins. In America, rails weighing as much as 137 lbs. per yard are now being used.

The Board of Trade has made a pronouncement against the employment of rails less than 90 lbs. per yard.

For a wheel flange ¾ in. thick, groove width should be 1⅛ in. on straight, and 1¼ in. on curves less than 75 ft. radius.

It is of importance that the profile of wheel tread and flange should accord to the shape of rail table and groove.

On curves of less radius than 50 ft. there is much grinding of wheel flange against both sides of groove which quickly widens under such wear; to allow for this the guard or lip on curve rails should be made thicker and higher and rails should be preferably of manganese steel.

Curves less than 100 ft. radius should be of spiralised or other easement form.

The top of guard or lip for straight-track rails is usually made slightly lower than the table, to allow for greater wear on latter, but the effect of this is very objectionable to vehicular traffic where the rail table is not sloped or coned.

The rail web should be as nearly as practicable under the centre of rail table, so that the resultant of forces, due to rolling load of car and lateral pressure of wheel flange, shall fall well within the rail base, otherwise there is a tendency for the rail to tilt sideways.

The base should be sufficiently wide to spread the superincumbent weight on to the underbed, and to resist the side-tilting motion.

The British Engineering Standards Association has issued a series (No. 2—1927) of fully dimensioned drawings for ' British Standard ' tramway-rail and fishplate sections, and also (No. 101—1929) for corresponding standard tyre profiles for tramcar wheels. A Report (No. 79—1927) has been issued by the Association on British standard special track-work for tramways.

Fig. 3, page 685, shows a section of a 103·7 lb. (No. 7) rail.

(Expert opinion, and the actual practice of some authorities, now favours the use of a deeper groove, viz. 1¼ in., than is shown in fig. 3.)

There are four sections of rails for straight tracks, with corresponding sections for curved tracks. Their general particulars, and those of fishplates, are as shown by the table below.

The affix C to the ' B.S ' number denotes that the rail is for use on curves, the difference between the straight-track and curve rails being that the groove is ⅛ in. wider and the guard or lip thicker and higher in the latter. All the sections have heads of similar profile as regards the groove and the angle of the rail-table. This profile gives a groove 1⅛ in. wide by 1¼ in. deep, measured from the highest point of the table, which has a radius of 9 ins. The guard or lip is $\frac{3}{16}$ in. below the highest point of the table. In the curve rails the groove is 1⅜ in. wide, and the lip is brought up level with the table.

BRITISH STANDARD SECTION TRAMWAY RAIL.

'B.S.' Section No. 7.—103·7 lbs. per yd.* (Superseding 'B.S.' Section No. 4.)

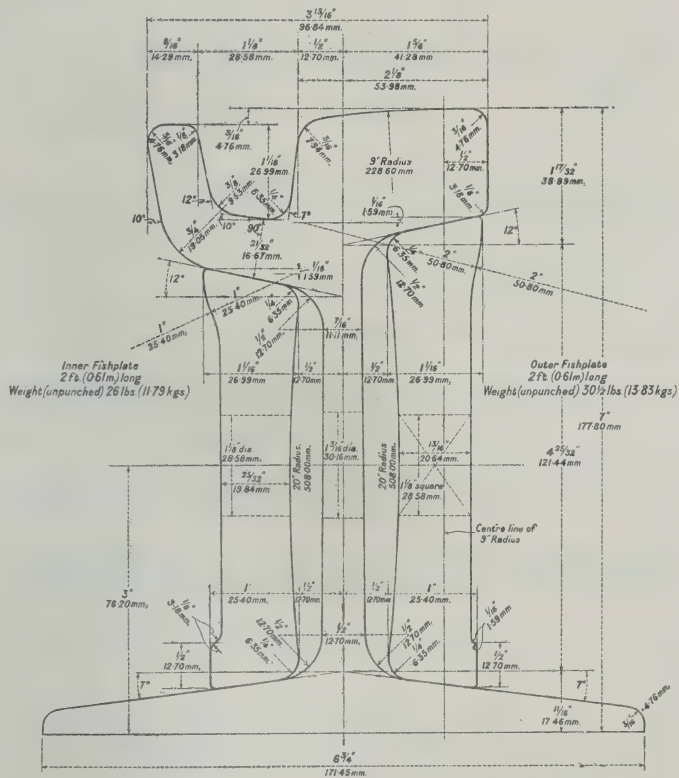

FIG. 3.

* 51·44 kgs. per metre.

Electrical resistance per yard of rail (single) = ·0000277 ohm = ·0487 ohm per mile = 11·8 times resistance of a copper conductor of same section.

The Association has likewise drawn up a Standard Specification for the manufacture of tramway rails, prescribing the chemical constituents, physical tests, etc. The principal provisions are briefly as follows:

Chemical composition.—Steel to conform to following limits:

	Bessemer Process.	Open-Hearth Process.	
	Acid.	Acid.	Basic.
	Per Cent.	Per Cent.	Per Cent.
Carbon . . .	0·50 to 0·60	0·60 to 0·70	0·60 to 0·70
Manganese . . .	Max. 1·0	Max. 1·0	Max. 1·0
Silicon . . .	,, 0·10	,, 0·10	,, 0·30
Phosphorus . .	,, 0·075	,, 0·06	,, 0·06
Sulphur . . .	,, 0·07	,, 0·06	,, 0·06

Manufacturer to furnish carbon and phosphorus determinations of each cast, and a complete chemical analysis for each rolling, or, if a rolling exceeds 100 tons, for each 100 tons or part thereof. Engineer may make independent analyses; in case of difference, samples may be analysed by an independent metallurgist, to be appointed by the Chairman of the B.E.S.A.

The following are abbreviated requirements:

Templates.—Two complete sets of templates are to be furnished, properly engraved with names of purchaser and manufacturer, 'B.S.' number of section, and date of contract.

Limits of variation.—Permissible variations are $\frac{1}{32}$ in. under or over total height, but $\frac{1}{64}$ in. only between fishing-angles.

Lengths.—Standard length of rail to be either 35 ft., 45 ft., or 60 ft., maximum proportion of short lengths being 5 and 2½ per cent. for the 35-ft., 5 and 2½ per cent. for the 45-ft., and 5 per cent. for the 60-ft. lengths.

A variation of ½ in. either way is permitted in the lengths. All short lengths to be painted at each end, the colour indicating the length.

Straightness and squareness.—All rails to be made properly straight and true in all directions when cold, and to be sawn or planed true and square, and burrs removed before leaving the works.

Branding.—A special brand is to be rolled on the web of every rail, to indicate that the rail is of 'British Standard' section and made under the conditions of the Standard Specification, also the number of section, weight, process of manufacture, manufacturer's name or mark, and year of manufacture. The number of cast or blow is also to be stamped near the end of each rail.

Falling Weight test.—A 5-ft. test-piece, head uppermost, is to be supported horizontally on steel bearings 3 ft. 6 in. apart at centres, and a tup, having 5 ins. radius face and weighing 1 ton, dropped on to it, midway between the bearings, from a height of 10 ft. If the rail fractures all from that cast may be rejected.

Tensile test.—From each 100 tons of rails a rail may be selected and a test-piece cut therefrom. It is to show an ultimate tensile strength equal to not less than 45 tons per sq. in., with an elongation of not less than 10 per cent. In case of failure the whole of the 100 tons may be rejected.

Bending.—From each 100 tons of rails a selected rail is to be tested by bending sideways to a curve of 30 ft. radius, and shall not show signs of cracking; if it does, the whole rolled from that cast may be rejected.

Holes in rails.—If required, each rail is to have holes made in it, without extra charge, for fish-bolts, electric bonds, and tie-bars. Those for the tie-bars may be punched, but all others must be drilled.

Notice and facilities for inspection.—Seven clear days' notice of the rolling of the first lot and three days for subsequent rollings is to be given; the inspector is to have access at all working hours to those parts of the mill where work under his inspection is being performed. The manufacturer is to provide all necessary apparatus in complete working order, and to provide all labour and reasonable assistance for making the specified tests. All rails accepted are to be stamped in the presence of the inspector.

Payment by weight.—Rails are to be paid for according to calculated weights before drilling or punching.

Fish-plates.—The chemical composition of the steel, tensile tests, and general conditions as to manufacture of fish-plates, are specified. Accuracy of fit between rails and fish-plates is regarded as of special importance, and sample joints are to be made whenever the engineer or inspector desires to test this.

Bending.—When cold and before being punched, the fish-plates shall be capable of being bent to a right angle round a bar 4 ins. in diameter without showing fracture.

Size.—Length for rail sections Nos. 6, 7, and 8, 24 ins., for No. 10, 18 ins., ends sawn square.

Holes are to correspond with those in the rails. All burrs are to be removed, and if fish-plates have been punched cold they are to be afterwards annealed. They are to be dipped into hot boiled linseed oil, and if required wired up in bundles. Payment is to be according to actual weight after punching.

(Copies of the complete specification and drawings can be obtained (post free, *5s. 4d.*) from the offices of the British Engineering Standards Association, 28 Victoria Street, S.W. 1.)

Notes on Chemical Constituents and Physical Tests of Tram-Rails.

Generally speaking, there are very wide variations in the specified stipulations as to the chemical constituents of steel for tramway rails, particularly with regard to the proportion of *carbon*, which may be regarded as the main hardening constituent, some engineers specifying this to be as low as from 0·28 to 0·40 per cent., while the highest extreme is from 0·60 to 0·70 per cent. It is questionable whether the latter stipulation always meets with full compliance.

Where British ores are employed, there are limitations in practicability of manufacture of very high carbon tramway rails.

If carbon is over 0·55, and especially if combined with high silicon, a somewhat brittle rail is likely to result.

Practical experiments under everyday conditions have shown that high carbon tram-rails have not given as good wear as those with moderate carbon.

Rails vary in hardness among themselves even when manufactured to the same specification and subjected to the same tests, and they show corresponding irregularities in their wear, which also varies greatly according to the situation in which rails are placed.

High carbon rails are specially liable to injury by injudicious thermal treatment in rolling.

Carbon and Manganese, particularly the latter, notably affect the electrical conductivity of steel, which in tramway rails usually varies from one-twelfth to one-fourteenth that of copper.

High manganese tends to coarse crystallisation, with resulting abrasion and flow of metal, or 'rolling out,' under heavy car traffic. This is often the cause of much trouble from hog-backing, &c.

Sulphur, when in moderate excess, is not particularly harmful, as hitherto generally supposed, but an excess of *Phosphorus* tends to brittleness.

A high percentage of sulphur mainly affects the rail-maker, causing red shortness and seamy metal with attendant difficulties in rolling.

In American standard specifications no limit of sulphur is specified.

Copper.—No limit necessary. It has been conclusively proved that it exercises no deleterious influence even when present in greater proportions than usually found in tram-rail steel.

Arsenic and Nickel.—Limiting proportions are occasionally specified, but for present processes of manufacture it is superfluous to mention these elements. There are proposals, however, to employ nickel to a greater extent in rail-steel making.

The processes usually employed in analysing the chemical constituents of steel are not so exact as for the physical tests. There is also considerable liability to personal error. The effects of segregation of the constituents often have an important bearing in the consideration of this question. Carbon is sometimes judged by the colour test, but more exactly by the combustion test.

Physical Tests.—The impact, or drop, test when conducted by a thoroughly competent inspector, is perhaps the most valuable of all tests for ascertaining the general quality and characteristics of the steel in tramway rails.

As deflection is in the nature of a measure of ductility of a rail, and as tramway rails are composed of chemical constituents with a view to securing extreme hardness in the steel—which is not compatible with great ductility—it is not usually considered desirable to exact a deflection test.

Steels of similar chemical constituents, but manufactured by different processes, will give somewhat different results in the physical tests. A high elastic limit is one of the most important properties of tram-rail steel, and can be obtained, combined with toughness, by suitable heat treatment.

The physical tests stipulated by specifications are often incompatible with the required chemical constituents of the steel and the processes to be employed in its manufacture.

The results of the chemical analyses and physical tests should be considered in conjunction.

Inspection.—It is of very great importance that there should always be careful inspection and testing of tramway rails, conducted by a thoroughly competent and reliable inspector, at the rolling-mills, before acceptance of deliveries.

Sandberg Rails.

The use of Sandberg silicon steel (silicon 0·3, carbon 0·5, manganese 1·1 per cent.) increases the life of rails by at least 25 per cent. If steel of the same composition is treated by a special process (Sandberg air-cooled steel), the life is said to be increased by 100 to 200 per cent., so far as experience has been obtained (*R. B. Holt*). The surface of rails can be hardened *in situ* by a patented process which has been adopted on several British tramways: this process diminishes the tendency to corrugation. The Sandberg sorbitic process has also been applied to tram-car tyres. The process needs to be correctly applied in order to obtain the best results.

Rolling-Mill Memoranda.

The Bessemer basic process of steel-making is now generally employed for the manufacture of tramway rails at English and Continental rolling-mills.

Rails are cut, while hot, by circular saw, to specified lengths, with a certain margin for shrinkage in cooling. They should be cut off quite square at the ends; the practice of undercutting below the head should not be permitted.

Very exact or dead lengths require to be planed in an ending or milling machine, and are usually subject to a slight extra charge.

Rails are straightened, while in a cold state, in a press.

45 ft. or 60 ft. are the most usual lengths. With the latter there are fewer joints, and they are generally preferred.

Density of Steel for Girder Tram-rails.

As a result of very careful and complete experiments and tests, undertaken at the instance of the Engineering Standards Association at the National Physical Laboratory, it was found that the average density of the steel in a large number of specimens of English-made tram-rails was 0·283 lb. per cubic inch.

Sectional area of rail in square inches=approximately one-tenth the weight of rail in lbs. per yard.

Rail Joints.

This detail is of the first importance, as the rail joints are the weakest part of the track and determine its life, being also the main factor in the cost of maintenance of the permanent way, and largely affecting the cost of upkeep of the rolling-stock and equipment.

A thoroughly strong and permanently rigid joint will maintain a smooth and quiet running surface, and will greatly lengthen the life of the rails, while assisting the electrical conductivity.

Fishplates alone, even when of the heaviest type, have proved inadequate to withstand the stress from the great vibration and pounding effect experienced from the running of heavy electrical cars, and the addition of flat plates under the rail-base has proved of no permanent advantage.

The very best type of joint should be employed, such as an efficient form of bridge joint. A type frequently adopted is the Cooper patent 'Anchor' joint, which is in the form of an inverted rail or joist riveted to the under side of the rail-base, thereby having the effect of doubling the depth of the rail about its weakest part. This device, in addition to providing an efficient connection between the rail-ends, also securely holds the rails down to the concrete foundation, thus keeping them rigidly in position and preventing springing, creep, etc. It is also of considerable value in providing a path for the electric return current.

Allied to the question of rail-joints is that of fixing down or anchoring the rails to the concrete under-bed, not only at the rail-ends, but at intervals intermediately. When rails are welded together, anchorage at close intervals is certainly a necessary accompaniment. With 'thermit welds,' anchors are placed 3 ft. from joints and then at distances of 13 ft. 6 ins. apart. At Leeds, with the 'thermit' process, the rails are anchored at 8-ft. intervals.

Taking into consideration the increased length of rails, the close-butting of ends, and other circumstances, this course is undoubtedly essential to provide against the effects from expansion and contraction, hog-backing, creep, springing, undulation, vibration, water-pumping, cold-rolling, spreading of gauge, and other causes tending to create movement in the rails.

The distance apart for intermediate anchors or holding-down devices varies from 3 ft. 6 ins., as at Hull, to 30 ft. There should be at least one intermediate with 45-ft. rails, and two with 60-ft. rails.

Rails should not be rigidly connected to each other across the track—as, for instance, by steel cross sleepers fixed under rail-base from rail to rail—as this is liable to cause waviness in the rail-table, due to unequal flexure in the rails.

Worn rails can be ground to shape *in situ* by a travelling apparatus, thus prolonging their life by several years. Worn joints, crossings, etc., can be built up to level by adding metal with the metallic arc.

Foundation.

In the most approved British methods of electric-tramway construction, the base of the rails is bedded on a foundation of concrete, composed of 4 parts of stone, 2 of sand, and 1 part of Portland cement, laid about 20 ins. wider than the gauge of the track, and 6 ins. in depth, a short length of some 3 ft. under the rail-joints being usually made from 3 ins. to 6 ins. deeper and of better quality concrete. The latter should be of clean aggregate mixed with good quality cement having somewhat quick-setting properties.

Sometimes the concrete is first laid, the rails being afterwards set, and packed to the required level with small crushed stone and cement, mixed dry. A more approved method is first to set the rails on blocks to the proper alignment and level, and to fit all the fastenings, afterwards placing the concrete in position under and around the rail-base, care being taken that there shall always be a sufficient 'head' on the upper surface of concrete above the rail-base.

At Hull, a longitudinal timber, 4 ins. thick and the width of rail-base, is interposed between the rails and the concrete. At Aberdeen, Birmingham, and Liverpool, on part of the track, cross-sleepers are used. Sleepers are no longer used in Glasgow.

The hollow on each side of the rail-web should be filled with a 'parging,' or rendering composed of 1 of cement to 4 of sand, laid to a vertical surface to pave against.

Rails should be laid so as to butt quite close at ends.

Paving.

Tar macadam and other forms of well-rolled smooth paving are coming much into use. Reinforced concrete is also being employed.

Points and Crossings.

Points and crossings should be of manganese steel throughout, or, if of the best crucible cast steel, then with specially hardened tongues. Renewable parts are of questionable value. Points should be about 12 ft. in length, having one road curved. The tongues should be at least 6 ins. longer than maximum wheel-base length of cars. Movable points should always be drained. Crossings should be of the 'leg' type, and from 7 ft. to 8 ft. long, according to angle number.

Drain-rails should never be used, but slots 9 ins. long cut in rail-groove at every low point, and trapped drain-boxes fixed and connected to sewer.

Cost of Construction.

Where the overhead running or trolley principle was adopted, the pre-war cost of construction of the permanent way varied approximately between 4,500*l.* and 6,500*l.* per mile of single track; this variation being mainly due to the different classes of paving used. Present prices are about 150 per cent. higher.

A fair general average of proportionate costs over a system may be taken as follows:—Rails and fastenings, including points, crossings and special work, 30 per cent.; paving (sett or wood) including concrete underbed, 45 (to 50) per cent.; labour, including cartage, 20 per cent.; bonding, 2 per cent.; watching and sundries, 3 per cent.

Tractive Resistance on Tramways.

The average pull required per ton of load to keep a car moving is 30 lbs. With exceptionally clean rails, as during a heavy rainfall, and with the rail grooves void of dirt, the pull may be as low as 20 lbs. per ton, or below this figure, approximating to the 10 or 12 lbs. of railway work. Again, a very dirty, clogged rail may demand more than the 30 lbs. Multiplying the pull by the speed in feet per minute gives the power in foot-pounds per minute, so that the horse-power is H.P. $= \frac{T \times W \times S}{33{,}000}$, where T is the pull per ton necessary, W is the load in tons, and S the speed in feet per minute. This rule gives the horse-power on the level. To find the power on a grade, the vertical rise of the car is found by dividing the speed of the car in feet per minute by the length of road in which there is a rise of 1 foot. The number of feet of vertical lift multiplied by the total weight in pounds gives the work done per minute against gravity, or $\frac{S \times W}{F}$, where W is the load, S is the speed, and F is the distance in which the road rises 1 foot. Thus on a 1 in 30 grade, F = 30. The addition of the two results gives the total horse-power. Track resistance is increased at curves, also increased horse-power is required during acceleration. The latter depends not only on weight of car as a whole, but also on moment of inertia of rotating parts.

Tramway Motors.

For a description of modern practice in tramway motor design and construction, see Section XXXV., 'Electrical Engineering.'

Tramway Motor Control.

Connections of Motors in Series-Parallel, with Cut-out of Resistances, on Metropolitan-Vickers Co.'s 'T' Type Tramway Controller.

The method now universally used for controlling the motors on an electric tram-car is that known as the series-parallel system. With this system the two motors are first thrown on to the line in series with one another and with a resistance. This resistance is gradually cut out by the operation of the controller until the two motors are left in series without any resistance in the circuit. The motors are then thrown in parallel with a resistance in the circuit, and when this resistance is finally cut out the motors are in full parallel.

Fig. 4 shows the various combinations as the handle of the controller is moved over.

First Point.—Current passes from the trolley through six sections of resistance, through Armature No. 1, and Field No. 1, thence through Armature No. 2, and Field No. 2 to earth.

Second Point.—Two sections of resistance are cut out.

Third Point.—Two more sections of resistance are cut out.

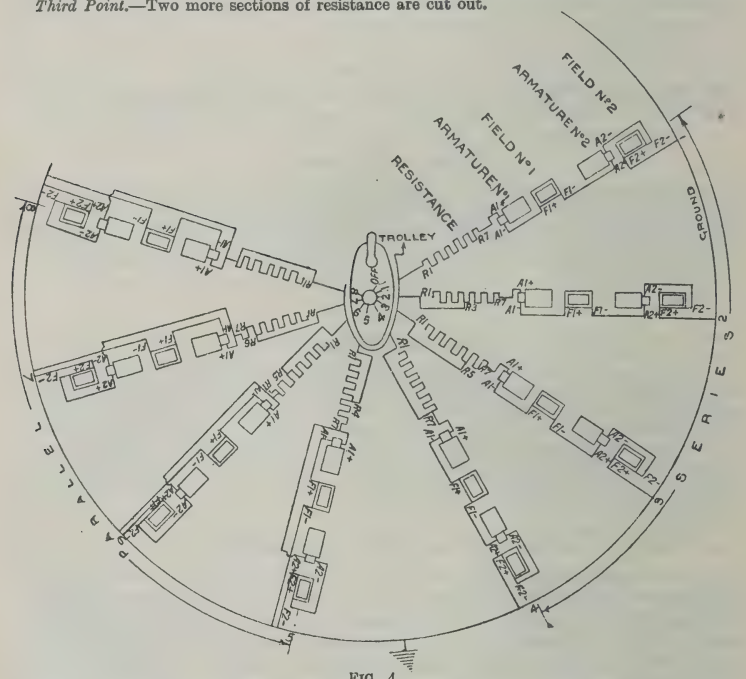

FIG. 4.

Fourth Point.—Two more sections of resistance cut out. The motors are now in full series on the line with no resistance in circuit.

Fifth Point.—Current passes from the line through three sections of resistance and thence to earth through the two motors in parallel. The armature and field of each motor remain of course permanently in series with one another on all combinations of the controller.

Sixth Point.—One of the sections of resistance is cut out.

Seventh Point.—Another of the sections of resistance is cut out.

Eighth Point.—The remaining section of resistance is cut out, leaving the two motors in full parallel on the line with no resistance in circuit.

General Electric Co.'s Tramway Controller Type KAI.

This drum type controller is arranged for the series-parallel control of two motors having a capacity not exceeding 70 B.H.P. each at the one-hour rating. It has four series, four parallels and seven braking notches, thus ensuring even acceleration and retardation. Shunt transition is employed between series and parallel. The connections are so arranged that it is possible to operate with one motor cutout. Braking may be accomplished both by rheostatic control and by electro-magnetic track brakes. The controller connections are arranged to afford an automatic run-back electric brake which comes into operation entirely independently of the action of the motor-man when the main handle is in the 'off' position. This feature prevents the possibility of the car running backwards on an incline. The controller is designed for operation on systems insulated on earth return.

Controller Drums and Handles.—The main handle is permanently fastened to the spindle of the main power drum, the reversing key only being removable. In order to render impossible improper operation of the controller, mechanical interlocking is provided which prevents the reverse spindle being moved unless the main power drum is in the 'off' position. It is impossible to move the main power drum unless the reverser is fully thrown into either the forward or reverse position. Arrangements are also provided which prevent the controller being moved on to the main power notches unless the motor cutout mechanism is positively locked in any one of its three positions.

The copper liners on the power drum are easily removable for replacement, and are provided with separately removable end segments where the arc rupturing takes place.

Contact Fingers.—The main contact fingers are of the compression spring type, the arrangement being such that the springs afford constant pressure between the contact tips and the segments of the drum while permitting of adequate variation in the depth of the stroke. This type of finger, being capable of individual adjustment, permits of the correct pressure being provided for each finger, thus eliminating undue wear and obviating heating of the contacts.

Magnetic Blow-out.—The controller is provided with individual magnetic blow-out coils to each finger. These coils are provided with steel cores which are connected to steel plates embodied in the blow-out shield partitions. These plates form part of the iron of the magnetic circuit for the blow-out coils, and as they extend throughout the greater part of the area of the shield partitions they distribute the magnetic flux between the partitions parallel to the shaft, and consequently at right angles to arcs formed between the fingers and drum segments irrespective of the position the arc may assume. This ensures the complete extinction of the arc under all operating conditions, and thereby reduces to a minimum the burning at the contacts.

Motor Cut-out.—The controller is provided with an external motor cut-out for the purpose of cutting out either motor without the necessity of removing the cover of the controller.

For this purpose an operating knob adapted to receive the reversing key is provided at the back of the controller, and by throwing this either up or down, No. 1 or No. 2 motor, as the case may be, is cut out of circuit, still leaving the other motor capable of being operated both for power and for rheostatic brake.

Weight.—The total weight of the controller complete is approximately 350 lbs., the overall dimensions being 42 ins. × 18 ins. × 9¾ ins. approximately.

BRAKING.

Electric braking consisted first of simple rheostatic braking, the drag on the motor armatures, acting as generators, causing the retarding force necessary. Resistance is inserted at first to prevent excessive currents and too severe strains on the motor windings, etc. This resistance is gradually cut out as the controller handle moves over the braking notches.

Electro-magnetic braking was added later, the braking effect being then partly electrical and partly frictional.

One weak point of electric braking was that, should the car be stopped when going up an incline, there was a tendency to run back, and then the electric braking had no effect unless the reversing handle was moved into the backward position. Omission to do this caused a number of accidents.

In the British Thomson-Houston Co.'s type B.510 controller, electric braking is obtained irrespective of the forward or backward position of the reverse handle or the direction of motion of the car. In the braking position the connections are such that the armature of No. 1 motor is in series with the field of No. 2 motor and *vice versa*.

In the English Electric Co.'s new controller, when the handle is in the off-position, electric braking immediately comes into operation if the car begins to run back.

The Metropolitan-Vickers Electric Co. have developed a new type of contactor-controller.

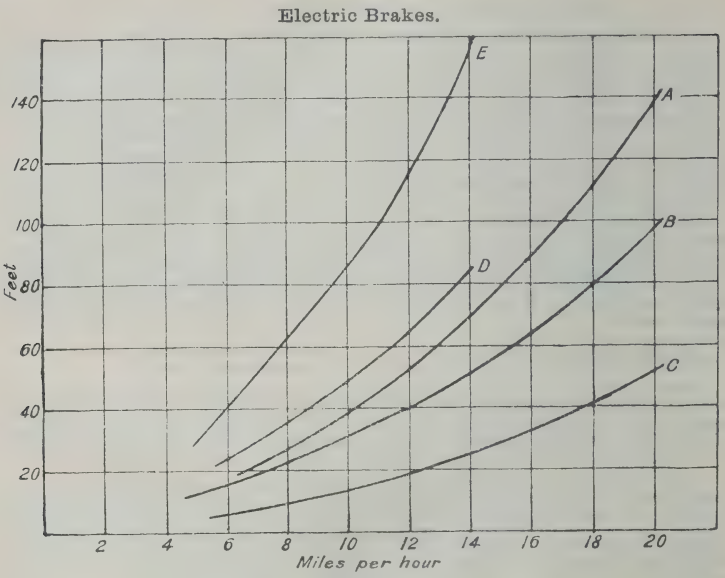

FIG. 5.

Fig. 5 shows the results obtained with tests on tramway cars fitted with various types of electric brakes. Tests A, B, and C were made under the supervision of the Special Committee on Brakes of the Tramways and Light Railways Association, tests D and E were made by Mr. A. L. C. Fell. Tests A, B, and C were made on a four-wheel car weighing 11 tons 9 cwt. loaded. Tests D and E were made on a bogie car weighing 13 tons with 6 persons. In every case the tests were made on a practically level track; in tests A, B, C, and D the rails were dry, in test E the rails were greasy. Tests A and E were made with a rheostatic brake, in tests B, C, and D the brake used was the Westinghouse electro-magnetic track brake, the track shoes being coupled to and acting with the ordinary brake shoes on the wheels. The results of each test are shown by a curve giving the speed in miles per hour at which the brakes were applied and the subsequent travel of the car in feet.

A comparison of curves D and B gives the relative effect of electro-magnetic track brakes acting under practically similar conditions on a bogie car and a four-wheel car. A comparison of curves A and B shows the behaviour of a four-wheel car under the action of a rheostatic brake and of a track brake in the case of ordinary service stops, while curve C shows the effect of a track brake on a four-wheel car in an emergency stop. In all these cases the rails were perfectly clean and dry. Curve E shows what may take place with a heavy car on a flat but greasy rail when controlled only by a rheostatic brake.

ELECTRIC EQUIPMENT OF TRAMWAYS.

Sectioning.

Trolley lines must be divided up into sections not exceeding half a mile in length by means of section insulators. The usual method of feeding the separate sections is to bring the supply cables to a small switch-board fixed in a cast-iron box near the poles carrying the section insulators. The supply cable is connected through a switch to a bus bar from which the four leads to the trolley lines are taken. Another method of feeding is to have a small section pillar in the middle of each section, into which the feeder is brought, and thence to feeder ears on the trolley wire. On the poles carrying the section insulators small iron boxes are fixed, carrying two single-pole switches connected to the section insulators. These switches are normally in the off position, so that in the event of a breakdown in the trolley line it is only necessary to go to one box in the centre of the section instead of two half a mile apart. In the event of failure on a cable, the section switches can be closed and the line run on the trolley wire alone.

All large and complicated junctions are generally isolated by means of section insulators on each line, placed as near the junction as possible, the junction being fed separately. This enables such a section to be isolated by the pulling out of one switch, and repairs can be made quickly and without shutting down the service.

Section boxes should be placed as close as possible to the poles up which the side-feed cables are carried. The simplest method of carrying the side-feeds from the box to the pole consists of a short piece of pipe passing from the section-box to the inside of the pole and held by lock-nuts to the section box. This method enables the cables to be easily withdrawn without disturbing the pavement, and also gets over the danger of the cables lying in water at the foot of the pole, as is frequently the case where they are carried underground.

The side-feed cables generally consist of rubber-insulated flexible-stranded cables, 2,500 megohm grade, and are protected by means of wooden brushes where they enter and leave the poles. The four cables should be tightly taped along their whole length to the span or bracket arm which carries them with 'P. & B.' tape or other weatherproof material. This gives them a neat appearance, and greatly increases the life of the cables. Paper-lead cables should on no account be used for side-feeds, as the lead frequently causes trouble. In some towns bare wires are used instead of rubber-covered cables, but the arrangement has an untidy appearance and possesses no advantages.

The system most in use at the present is known as the single-trolley system, the current being collected from the overhead wires and returned through the rails. In some few cases, where the earth-return current is likely to affect delicate scientific instruments, two overhead wires are carried over each track, one being the feeder and the other the return. This system, however, involves complications at junctions owing to the necessity of extra insulation between the feed and return wires, and the large number of wires required.

Trolleys.

The trolley with outside springs is the most simple form of trolley, as all springs are easily examined and adjusted. The cable is carried down the inside of the trolley arm to the bottom of the standard. The connection to the car leads is made by means of revolving rings or fixed-ring collector and a revolving brush, which allows the arm to make a complete revolution. In the Blackwell trolley with inside springs the springs are entirely enclosed, and are easily adjusted by means of one tension rod. This type has the advantage of taking up less room than the outside spring type.

The Trolley Wheel.

Trolley wheels should be of a good quality metal, but not too hard, as a worn wheel can be more easily replaced than a worn wire. Some trolley lines have been ruined by the manager, or other person responsible for the trolleys, endeavouring to get a high mileage out of the wheels.

The trolley wheel is usually about 4 ins. over all in diameter, of gun-metal or other copper alloy, and is fitted with a bush filled with some graphitic compound. The following are the dimensions recommended by the British Engineering Standards Association (No. 23—1905) as the section of the standard trolley wheel grooves (fig. 6): Width in inches = $1\frac{3}{8}$; depth in inches = $\frac{3}{4}$; radius in inches = $\frac{3}{16}$: angle in degrees = 65°.

Fixed or swivel trolley heads may be used. In Glasgow a fixed head is adopted.

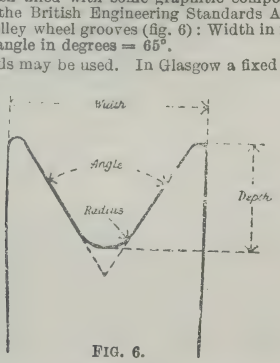

FIG. 6.

Sliding trolley heads are now being tried instead of wheels, with good results. The number of dewirements is greatly reduced, and less damage is done to the overhead equipment on dewirement. But the wear on the trolley wire is about doubled unless the wire is lubricated.

Overhead Construction.

The types generally in use are span, single-side bracket, double-side bracket, and centre pole. The span system is the best from the line point of view, as it allows the greatest flexibility, and also allows the wire to be placed centrally over each track, thus ensuring an even wear on the wire and a smaller tension on the trolleys. It has, however, the disadvantage of requiring standards

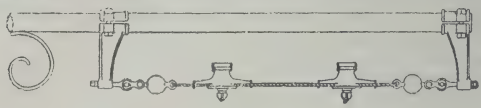

FIG. 7.

on both sides of the streets; and in many cases this is impossible owing to telegraph lines or other causes. Double bracket arms are used in some cases where the lines are laid close to the kerb on both sides and where span wires across the street would be of excessive length.

The single-side bracket is the form of construction most generally in use where economy is of importance and in cases where there are difficulties in obtaining room for structures on both sides of streets. Side brackets up to 22 ft. long have been used in some instances, but such long arms should only be used in very exceptional cases. The Board of Trade Memorandum (see page 700) limits the length of the arms to 16 ft. maximum. Where bracket arms are used, the trolley wire should be suspended by means of flexible suspensions, as in fig. 7. These consist of a short length of stranded-steel wire strained between two suitable malleable cast-iron or wrought-iron brackets bolted to the bracket arm. This length of wire should not be strained too tight, as it then becomes a practically rigid suspension; neither should it be left sufficiently slack for there to be any danger of the line being lifted by a trolley so that the insulator casting comes in contact with the bracket, and so cuts out the second insulation.

Trolley Wire Fittings.

The standard practice is to use double insulation in all cases on trolley lines, the usual method being an insulated bolt fitted into the hangers, the second insulator being at each end of the spans. All spans should be fitted either with one or two strain insulators in order to provide adjustment of the span wires. Triple insulation is now called for by the Board of Trade between any gas or electric lamp bracket attached to pole and trolley wire. Composition insulation is being largely replaced by porcelain. The most usual types of insulators are the straight line hanger and the double and the single pull-off for use on curves. The metal portion of the insulators is either of malleable cast iron or gunmetal, the latter being more expensive in first cost, but cheaper to maintain, as it does not require painting. In the Blackwell type of section insulator it is unnecessary to anchor the trolley wire over the top of the insulator.

The usual method of attaching the trolley wires to the suspension insulator is by sweating them into gunmetal ears. Where sweating is adopted the ears should be accurately milled out to take the wire, and the lips of the ears which clip round the wire should be carefully hammered over before soldering, and the ears dressed off to a feather edge after soldering, great care being taken not to notch the wire where it leaves the ear. In all cases it is absolutely essential that the wire should be held in a strong soldering clamp during the whole process of soldering until the ear is cooled. Unfortunately this practice is insisted on only in cases where the work is carried out by experienced contractors; and in many cases where corporations do their own work the sweating clamp is considered unnecessary, with the result that breakages of the wire at ears frequently occur. The sweating of the ears naturally causes the wire to be annealed, and this also is a cause of breakages.

The most satisfactory arrangement is to have the ears carefully hammered along the wire and the ends dressed off and left unsoldered. For some reason, however, this method is seldom specified, though not infrequently it is adopted in actual construction. In many cases mechanical bars are used. These are made in two halves, bolted together, and grip the trolley wire by means of a V-shaped groove drawn in the wire slightly above the centre line. This method facilitates erection, avoids softening the wire by sweating, and gives a straighter path to the trolley at the ears. It has, however, the disadvantage that the wire has to be annealed in order that the groove may be drawn into it, and the breaking strain of a grooved wire is less than that of a circular wire; there is also a tendency for the groove to turn over between the points of support, causing the wheel to run badly and frequently to leave the wire on curves.

Guards should be fixed at all frogs and on both sides of all crossings to prevent the trolleys jamming in the angles, as, in addition to their being a great safeguard, they help to preserve the wire, as the wear is taken up by the mechanical ears which support the roller bars, and these are easily renewable.

Poles.

Poles are usually 31 ft. long, and are planted 6 ft. in the ground, sufficient rake being allowed in erection so that the pole stands nearly vertical with a slight backward rake when the span and trolley wires are on. The amount of rake for a 36-ft. road in good ground should be about 6 ins., but the actual rake required varies with every class of ground, and can only be successfully estimated by experienced men. The holes should have a sufficient diameter to allow of six inches of concrete round the pole in good ground; this must be increased in bad ground or at places where additional loads are imposed due to bridles, extra long spans, etc. The poles should be planted on circular discs of concrete, or on flagstones or cast-iron plates dropped into the holes to prevent the poles cutting into the ground during erection. The holes should be filled in with 6 to 1 concrete, well rammed.

In order to prevent corrosion, all poles should be coated inside and for a distance of 8 ft. from butt outside with hot tar or Angus Smith composition.

In some coast towns corrosion, and a consequent loosening at the joints, sometimes occurs.

One-piece poles or poles welded smoothly at joints are being adopted, as in Edinburgh and Aberdeen.

In the specification for tramway poles, the light pole is suitable either for short side brackets or centre pole work, the medium pole for long brackets or span construction, and the heavy pole for anchors and pull-off poles. Three-section poles are generally used, as they are cheaper and more reliable than taper poles. Owing to the irregularity of the taper, the fitting of brackets, pole straps, etc., is extremely difficult with taper poles, and their appearance when erected hardly differs from the three-section pole.

Specification for Poles.

BRITISH STANDARD SPECIFICATION FOR TUBULAR TRAMWAY POLES.*

(No. 8—1927.) (*Abstract.*)

1. The poles shall be of wrought steel free of all defects, and shall be of four classes: light pole, medium pole, heavy pole, and extra-heavy pole.

2. The poles may be made of three separate sections (sectional poles) swaged together when hot so as to make a perfect joint; or they may be made in one piece with two reduced parallel steps (stepped poles). Poles of both types shall be made either by the hot-rolled weldless process or the lap-weld process, of steel of a tensile strength of not less than 24 tons nor more than 42 tons per square inch. The lap-welded seams in the sections shall be set at an angle of one hundred and twenty degrees (120°) to each other.

3. The overall length of poles of all classes shall be 31 ft.

4. The length of the telescope joint in the sectional poles shall be 18 ins., and the upper edge of each step shall be chamfered off at an angle of not less than 30°.

5. The visible length of the sections or stepped portions shall be :—

Top section	7 ft.
Middle section	7 ft.
Bottom section	17 ft.

6. The outside diameters of the four classes of poles shall be as follows :—

Class.	Top Step or Section.	Middle Step or Section.	Bottom Step or Section.
Light	5½ ins.	6½ ins.	7½ ins.
Medium	6½ ins.	7½ ins.	8½ ins.
Heavy or Extra-Heavy	7½ ins.	8½ ins.	9½ ins.

The variation in diameter shall not exceed $\frac{1}{16}$ in.

* By permission of the British Engineering Standards Association.

7. The minimum thickness of metal in any pole shall be as follows :—

SECTIONAL POLES.

Class.	Top Section.	Middle Section.	Bottom Section.
Light	$\frac{4}{32}$ in.	$\frac{4}{32}$ in.	$\frac{5}{16}$ in.
Medium	$\frac{5}{32}$ in.	$\frac{5}{32}$ in.	$\frac{11}{32}$ in.
Heavy	$\frac{7}{16}$ in.	$\frac{11}{32}$ in.	$\frac{13}{32}$ in.
Extra-Heavy	$\frac{9}{16}$ in.	$\frac{11}{16}$ in.	$\frac{9}{16}$ in.

STEPPED POLES.

Class.	Top Step.	Middle Step.	Bottom Step.
Light	$\frac{5}{16}$ in.	$\frac{5}{16}$ in.	$\frac{5}{16}$ in.
Medium	$\frac{11}{32}$ in.	$\frac{11}{32}$ in.	$\frac{11}{32}$ in.
Heavy	$\frac{13}{32}$ in.	$\frac{13}{32}$ in.	$\frac{13}{32}$ in.
Extra-Heavy	$\frac{9}{16}$ in.	$\frac{9}{16}$ in.	$\frac{9}{16}$ in.

The tolerance shall be 5 per cent. under the above thicknesses.

8. The completed poles shall be straight and true over their entire length to within $\frac{1}{4}$ in.

9. Five per cent. of each class of sectional pole shall, if required, be subjected to the following drop test :—

The pole shall be dropped vertically, butt downwards, three times in succession, from a height of 6 ft. on to a hard wood block 6 ins. thick laid on a concrete foundation, without showing any signs of telescoping or loosening of joints.

10. Five per cent. of each class of pole shall be subjected to the following bending tests :—

The pole shall, in each case, be fixed horizontally and rigidly supported for 6 ft. from the butt, and loaded, as a cantilever, at a point 18 ins. from the top, the load being applied at right angles to the axis of the pole. Upon the application of the following loads, the temporary deflection and permanent set, measured at the point of application of the load, shall not exceed the figures stated in the table.

Class of Pole.	Load in lbs. for temporary deflection not exceeding 6 ins.	Load in lbs. for permanent set not exceeding $\frac{1}{2}$ in.
Light	750	1,000
Medium	1,250	1,750
Heavy	2,000	2,500
Extra-Heavy	2,750	3,250

11. In the event of any pole of the above-mentioned 5 per cent. not fulfilling the test requirements, a further 5 per cent. shall be subjected to the tests enumerated. Should any further failure occur, the whole parcel from which the poles have been selected shall be liable to rejection.

APPROXIMATE WEIGHT OF POLES.

The weight of the poles referred to in the Specification may be assumed to be approximately as follows :—

	Light.	Medium.	Heavy.	Extra-Heavy.
Sectional Poles	700 lbs.	872 lbs.	1,130 lbs.	1,437 lbs.
Stepped Poles	674 lbs.	851 lbs.	1,132 lbs.	1,538 lbs.

Trolley Wire.

Trolley wire is usually 0 (·324 in.), 00 (·348 in.), or 000 (·372 in.) S.W.G., of hard drawn copper; conductivity should be 98 per cent. of pure copper; it should bear an elongation of 1½ per cent. in 10 inches, a breaking strain of 25 tons per square inch, and 20 twists in a length of 12 inches. Copper cadmium is also being used. Its conductivity is about 93 per cent. of Matthiessen's Standard and its breaking stress about 30 tons per square in. At curves and places where wear is severe, phono-electric wire is used; its conductivity is, however, low, usually 50 per cent. to 60 per cent. of Matthiessen's Standard.

The Engineering Standards Association recommends that the tensile breaking strength should be not less than 24 tons per square inch up to No. 00 S.W.G., and not less than 22 tons above that gauge.

If

L = distance in feet from pole to pole; l = actual length in feet of one span of trolley wire; d = dip in feet; T = tension in lbs. in trolley wire at point of support; w = weight in lbs. per foot of wire; then

$$d = \frac{L^2 w}{8T}\ ;\ T = \frac{L^2 w}{8d}\ ;\ l = L + \frac{8d^2}{3L}\ ;\ d = \sqrt{\frac{3Ll - 3L^2}{8}}.$$

If

e = expansion coefficient per F° = ·00001; $c°$ = change of temperature; then $l \pm c°e$ gives the new length on change of temperature = $c°$, from which the new dip d may then be calculated, or the tension T for any dip. In these formulæ the effect of wind pressure is neglected.

The lowest point of the wire should not be less than 17 feet from the road surface.

Span Wire.

The steel wire rope to form spans for carrying trolley wire is usually formed of a galvanised strand of 7 No. 12 S.W.G. or No. 7 No. 15's. The 7/12 is usually specified to bear a breaking strain of about 4,600 to 5,000 lbs. When the 7/15 wire is used it is of much harder material, and weighs 225 lbs. per 1,000 yards. The only objection to the small wire of high tenacity is the difficulty of forming the eyes over the thimbles and nozzling the ends.

Guard Wire.

Guard wire when single is No. 8 S.W.G. steel, and weighs 215 lbs. per 1,000 yards, but it is often of stranded steel. Guard wire brackets in their plainest form are T's of ¾ in. iron pipe clipped on bracket arms. In span systems guard wire is carried by special guard wire spans. The Board of Trade have an explanatory memorandum on 'Guard Wires on Electric Tramways.'

Strength and Conductivity of Wires.

Material.	Conductivity.	Breaking strain, Lbs. per Sq. In.
Commercial copper	98–99	33,000
Hard drawn „	96–97	60,000–65,000
(1) Silicon bronze	97	63,200
(2) „ „	80	76,000
(3) „ „	45	110,000
Phosphor „	26	101,000
Annealed iron	14	55,000
High carbon steel	10–12	120,000–130,000

Rail Bonding.

Except in those comparatively rare cases where a double trolley wire is employed, the rails are made use of as return conductor, and means have to be taken to connect adjacent rails so as to provide an unbroken electrical conductor. To effect this object the rails are bonded with copper, various types of bonds being employed.

The 'Chicago' Bond.

Fig. 8 shows the general design of this bond, which consists of a copper rod having tubular or thimble-shaped terminals bent at right angles to the rod, the whole being composed of one solid piece of copper. The terminals are inserted into holes in the web of the rail, and the slit in the end of the terminal is spread or clinched over the rail with a hammer and punch. A drift

pin, larger in diameter than the opening in the terminal by about one-sixteenth of an inch, is then driven in. This permanently expands the terminal and wedges it into contact with the surface

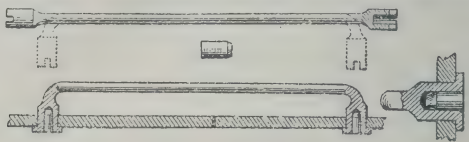

FIG. 8.—Chicago Bond.

of the hole in the web of the rail. The usual length of bond is 30 ins. The depth of the hole in the terminal in all sizes of bond is 1 inch. The size of conductor used depends upon the weight of rail and the current to be carried.

TABLE SHOWING STANDARD DIMENSIONS OF CHICAGO RAIL BONDS.

Size of Wire, B. & S. Gauge.	Diameter of Hole in Rail into which Terminal of Bond fits.	Diameter of Hole in Terminal.	Sectional Area of Rail Bond.	Diameter of Pin.
	Ins.	Ins.	Sq. Ins.	Ins.
0000	$\frac{7}{8}$	$\frac{7}{16}$	·166	$\frac{1}{2}$
000	$\frac{3}{4}$	$\frac{3}{8}$	·132	$\frac{7}{16}$
00	$\frac{5}{8}$	$\frac{5}{16}$	·104	$\frac{3}{8}$
0	$\frac{1}{2}$	$\frac{1}{4}$	·083	$\frac{5}{16}$

The 'Crown' Bond

FIG. 9.

This is a development of the 'Chicago' bond, the conductors being stranded to afford the flexibility necessary for expansion in a conductor of considerable cross-section dimensions. Fig. 9 shows two of the many different designs in which this bond is made. The terminals have the same dimensions as those in the corresponding 'Chicago' bond.

The 'Neptune' Rail Bond.

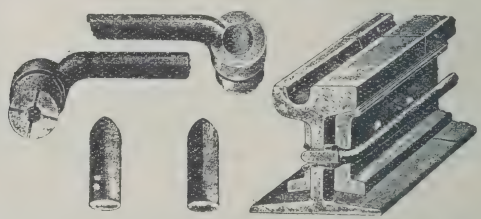

FIG. 10.

Another form of bond, the 'Neptune,' fig. 10, is similar to the 'Chicago,' but the drift pin is driven in the same direction as the bond is inserted, thus safeguarding the bond against being driven out.

The 'Columbia' Rail Bond.

A feature in this bond (fig. 11) is the few parts of which it consists. When installed, owing to the pressure exerted between the head and the thimble, and also the fact that they are of the same kind of metal, the two become one, both electrically and mechanically. It therefore has

all the advantages which may be claimed for a one-piece bond, and at the same time can be satisfactorily installed as no riveted bond can be. The contact of the rail and bond is made by a wedge expanding the thimble against the hole in the rail. By using a press, exactly the right pressure is exerted. One blow of a hammer too many or too few frequently spoils contact. As

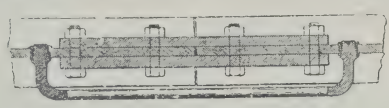

FIG. 11.

the bond is wedged both ways it cannot get loose, as, owing to the fact of its being pressed in, it is sure to make a perfect contact, and cannot be so over-stretched by hammering as to be ready to fall out at the end of a few weeks. It is essential that the hole in the rail should be clean, and the copper bright also. Bonds ought to be inserted at once after the rails are drilled, no time being allowed for rusting to commence.

WELDED BONDS.

The best of all methods of attaching bonds to rails is by electric welding. On this system short bonds can be used, welded into the head or base of the rails outside the fish-plates, or to the webs inside them; the cost of the bond and its attachment is small, and the high conductance of the joint is permanently ensured. Welding bonds to rail is found to weaken the web of rail slightly.

Rail Welding.

Tramway rails are united into continuous lengths by welding. There are several systems in use for welding rails.

THE FALK CAST WELD.

This consists in casting round the cleaned ends of the two rails a mass of cast iron from a portable cupola. Being buried up to their top table, welded rails are held against contraction from cold, and the full stress does not come upon the weld. Expansion in hot seasons is impossible, and the rails are held against lateral buckling by the support of the paving.

ACETYLENE WELDING.

Acetylene welding by the D.A. system (*The Dissolved Acetylene Co., Ltd.*, now trading as *Allen-Liversidge Ltd.*) has been made considerable use of. The method consists essentially in reinforcing the joints by means of a pressed steel shoe placed on the flange of the rails at the joint and welded to the same so as to constitute a hollow beam which increases the moment of inertia about the joint, and correspondingly diminishes the bending caused by the passage of rolling stock. Many joints of this type have been fitted in France and Algiers and in South America.

THERMIT WELDING.

In Thermit welding a mould is fitted round the rails at the joint, and into it is run molten metal from a conical crucible, which is first filled with a mixture of powdered aluminium and iron oxide. The two are intimately mixed, and heated at a point by a special ignition powder. At the temperature produced by igniting this powder, the aluminium reacts very energetically with the oxygen in the iron oxide. The reaction spreads rapidly throughout the mass in the crucible, and produces a quantity of pure superheated liquid metal, covered with a slag of alumina. The temperature set up by the reaction has been ascertained to be about 5,400° Fahr. The crucible is a lined sheet-iron cone. It is suspended over the joint to be welded, and when the reaction is complete it is tapped, the metal running into the mould, followed by the superheated liquid slag, which covers the head of the rail, and raises it to a welding temperature. The rails are then drawn together by suitable clamps, with the result that the base and web of the rails are welded by fusion with the liquid Thermit metal, and the head is butt-welded.

For extra high-carbon rails, the difficulty of butt-welding has been overcome by the use of a special shim, which is inserted between the rail-ends, and ensures a perfect butt-weld at the head.

Thermit welding is often used on new work, partly because electric power is not available.

ELECTRIC WELDING.

Electric welding has been very widely used, especially in the United States. Two methods have been developed—spot-welding and arc-welding. In the former, bars are placed on both sides of the rails at the joint, and are welded to the webs of the rails by heating them with a

very strong current at low pressure, obtained from a transformer, after which the parts are tightly pressed together. These welds are made at several points along the bars. In the latter process, steel plates are welded to the head and foot of the rails with the electric arc, taking the place of fish-plates. In both cases additional bonds are unnecessary, but one 'Neptune' rail bond per joint is often provided. Manganese steel rails can be successfully welded with the electric arc.

(See also 'WELDING,' Section XL., Part II.)

Tramway Track Leakage.

Experiments made by the U.S. Bureau of Standards show that tramway tracks laid on concrete have a low resistance to earth—from 0·2 to 0·5 ohm per 1,000 ft. of single track. With crushed stone ballast under a concrete road-bed the resistance is about three times as great, while with crushed stone ballast with 'Tarvia' finish the resistance is 2 to 3 ohms. Track laid on wooden sleepers embedded in earth has a resistance of 1 to 1·5 ohms. Open track on sleepers laid on good stone ballast has a resistance of 10 to 15 ohms or more in dry weather, 3 to 5 in wet weather, per 1,000 ft. of single track. Chemical salts used to preserve the sleepers greatly reduce the resistance.

Cables.

In English tramway work the cables must be buried. There are four systems in use for buried cables. First, the system of drawing into buried cast-iron pipes. In this system spigot and socket pipes are employed, usually 2 ins. and 2½ ins. inside diameter. A 2-inch pipe 6 ft. long will weigh 48 lbs., a 2½-inch pipe 9 ft. long will weigh 81 lbs. About 2 to 2½ lbs. of lead are required to pour each joint. The pipes terminate in buried brick chambers in which they are finished with trumpet-shaped ends to facilitate drawing in. On curves the pipes may be slightly curved with advantage, but it is usual to lay the pipes round the curve in an equiangled polygon and to use manhole boxes at such intervals that no length of pipe has a versed sine above 12 ins. Soapstone powder is used as a lubricant. The brick chambers should be built on a good concrete bed with a cement collar joint, and they may advantageously be tarred over outside to render them waterproof. The pipes are bonded across the boxes with a stout iron wire to render them electrically continuous; the boxes have a cast-iron top frame with luted cover. These boxes must be placed at such distances apart that excessive stress is not brought upon the cables when hauling them in. The cables should be gripped by their cores. In place of pipes earthenware conduits are often employed of rectangular or hexagonal shape, in short lengths and cemented at the joints, also terminated in brick chambers. In the solid system the cables are laid in troughs of wood or sheet steel, and melted bitumen is poured over them so as to completely enclose them in a casing of bitumen. Cables are sometimes simply buried in the earth. The best cables are insulated with paper and sheathed in lead about $\frac{1}{12}$ in. to $\frac{1}{5}$ in. thick, squirted on under pressure. In whatever way laid the cables are brought up in their respective casings through the base of the section box, in which they are connected to the bus bars by switches, so that the cables may be switched out of the circuit in lengths of about half a mile. In the section box are placed the switch terminals of the trolley feeders, which can also be cut out of circuit in half-mile lengths. The trolley feeder cables are carried up inside the next pole, and in the Booth-Dickinson system, brought through the top finial, then down the pole and along the span wire or bracket arm to the trolley wire terminals on the section insulator. Test and telephone wires are usually laid up in one cable and similarly laid in pipes, etc. Sometimes a telephone wire is carried overhead on insulators fixed to the poles. In laying cables and making joints the utmost care is necessary not to expose cable ends to the atmosphere excessively. Tents must be used in wet weather, but it is better to do the work in dry seasons. Cable ends must be well stoppered. It is preferable to have the cable ways under footpaths. The topmost pipe must not be nearer the surface than 18 ins. when laid in the road. Cast-iron pipes or sheet steel conduit must be dipped in Angus Smith compound of a non-brittle variety when cold, and cast-iron pipes should be dipped until they themselves are as hot as the boiling compound. The lead sheathing of cables must be electrically bonded past the manhole boxes and connected to the rails at the nearest point to the power station.

In Glasgow, cables are drawn into ducts, usually fire-clay; sets of 3 or 6. Ducts are laid in the 4-ft. way between the tracks. Manholes are not more than 400 ft. apart. All solid laid cables are gradually being replaced by duct-laid.

ABSTRACT OF BOARD OF TRADE MEMORANDUM, REGARDING DETAILS OF CONSTRUCTION AND EQUIPMENT FOR TRAMWAYS AND LIGHT RAILWAYS LAID ON PUBLIC ROADS.*

Clearance.

There should be at least 15 ins. between the sides of passing cars and also a similar space between the side of a car and any standing work, such as lamp, telegraph and trolley wire posts in a street.

* The functions of the Board of Trade are now exercised by the Ministry of Transport.

There should be at least 15 ins. between the side of a car and the kerb, whether on straight or curved roads.

The clearance between the top deck of cars and the underside of bridges should not, if possible, be less than 6 ft. 6 ins. Where this clearance cannot be obtained special precautions in working will be required, but in no case will less than 6 ft. be accepted with uncovered cars.

Posts and Brackets.

Where bracket arms 16 ft. in length will not suffice, it is desirable that span wire construction should be used.

The overhead conductors used in connection with the working of the tramways should be securely attached to supports, the intervals between which should not, except with the approval of the Board of Trade, exceed 120 ft., and the overhead conductors should be in no part at a less height from the surface of the street than 20 ft., except where they pass under bridges.

The overhead conductors should be divided up into sections not exceeding (except with the special approval of the Board of Trade) one-half of a mile in length, between every two of which should be inserted an emergency switch so enclosed as to be inaccessible to pedestrians.

Poles supporting gas lamp brackets should be efficiently bonded to the rails.

Permanent Way.

The weight of rails should not be less than 90 lbs. per yard, 100 lbs. being preferred.

The groove of the rail should not exceed 1⅛ in. in width, but a groove not exceeding 1¼ in. will be accepted on curves of less than 150 ft. radius.

Cars.

Of existing types of lifeguard, the 'trigger' is the pattern which is preferred. The hanging gate should be as close to the ground as possible, and there should be at least 3 ft. between it and the front of the guard. Both the guard and the gate should be at least as wide as the outside of the frame of the truck. The tray of the guard should be provided with a spring so as to hold the front edge down to the surface of the roadway when the tray is dropped.

All railings should be connected with earth.

All electrical conductors fixed upon the cars in connection with the trolley wheel should be formed of flexible cables protected by indiarubber insulation of the highest quality and additionally protected wherever they are adjacent to any metal so as to avoid risk of the metal becoming charged.

The trolley standard of every double-deck car should be electrically connected to the wheels of the car in such manner as either to prevent the possibility of the standard becoming electrically charged from any defect in the conductors contained within it or in the event of the standard becoming electrically charged to give a distinctive and continuous warning signal to the driver or conductor. The signal may be a red lamp bridged with a suitable fuse or (preferably) an audible signal. The signal device should be tested at least once a week.

In the Board of Trade Memorandum dealing with guard wires on electric tramways the following regulations are laid down :—

Each guard wire must be well earthed at one point at least, and at intervals of not more than five spans. The resistance to earth must be such that a short circuit between a guard wire and a trolley wire will open the circuit breaker.

The earth connection should be made by connecting the support to the rails by means of a copper bond. When first erected, the resistance to earth of the guard wires should be tested, and periodical tests should be made to prove that the earth connection is efficient.

Guard wires should be, in general, of galvanised steel, but in manufacturing districts in which such wires are liable to corrosion bronze or hard drawn copper wires should be used.

The gauge of the guard wire must be such that it will carry, without fusing, a current 50 per cent. greater than that required to open the circuit breaker, and the guard wire must be maintained in such a manner that it will at all times meet these requirements.

The supports for the guard wires should be rigid and of sufficient strength for their purpose, and at each support each guard wire must be securely bound in or terminated.

The rise of the trolley boom should be so limited that if the trolley leaves the wire it will not foul the guard wires.

A Summary of the Board of Trade Regulations for Electric Tramways.

The following is a brief summary of the principal regulations affecting electric traction :—

When any rails on which cars run, or any conductors laid between or within 3 feet of such rails, form any part of a return, such part may be uninsulated. All other returns, or part of a return, shall be insulated, unless of such sectional area as will reduce the difference of potential between the ends of the uninsulated portion of the return below 7 volts.

Where any uninsulated conductor laid between or within 3 feet of the rails forms any part of a return, it shall be electrically connected to the rails, at distances apart not exceeding 100 feet, by means of copper strips having a sectional area of at least $\frac{1}{10}$ of a square inch, or by other means of equal conductivity.

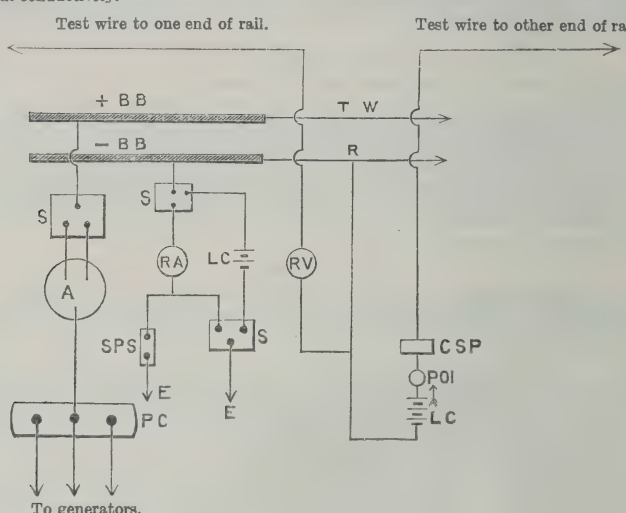

FIG. 12.—Diagram of Board of Trade Switchboard.

A, Ammeter reading $\frac{1}{10}$ — 3 and $\frac{1}{2}$ — 10 as.; B B, Bus bars; R, Return; T W, Trolley wire; S, Two-way switches; R A, Recording Ammeter 2 to 25 as.; R V, Recording voltmeter 2 to 10 v.; L C, Leclanché cells; S P S, S.P. switch; E, Earth; P C, Three-way plug connections; P O I, P.O. indicator; C S P, Contact of sensitised paper.

All uninsulated returns shall be connected to the negative pole of the generator; the negative terminal of the generator shall be also connected through a current-indicator, mentioned below, to two separate earth connections, which shall be placed not less than 20 yards apart. This clause enacts that the two earth connections may be replaced by making one connection to a water-pipe of not less than 3 inches internal diameter, provided that permission be obtained from the owner of the water-pipe and the person supplying the water.

The earth connections referred to in this regulation shall be constructed, laid, and maintained so as to secure electrical contact with the general mass of earth, and so that an electro-motive force not exceeding 4 volts shall suffice to produce a current of at least 2 amperes from one earth connection to the other through the earth, and a test shall be made at least once in every month to ascertain whether this requirement is complied with.

When the return is partly or entirely uninsulated the company shall, in the construction and maintenance of the tramway, (*a*) so separate the uninsulated return from the general mass of earth and from any pipe in the vicinity, (*b*) so connect together the several lengths of the rails, (*c*) adopt such means for reducing the difference produced by the current between the potential of the uninsulated return at any one point and the potential of the uninsulated return at any other point, and (*d*) so maintain the efficiency of the earth connections specified in the preceding regulations as to fulfil the following conditions, viz. :—

(i.) That the current passing from the earth connections through the indicator to the generator shall not at any time exceed either 2 *amperes per mile of single tramway line or* 5 *per cent. of the total current output of the station.*

(ii.) That if at any time and at any place a test be made by connecting a galvanometer or other current indicator to the uninsulated return and to any pipe in the vicinity, it shall always be possible to reverse the direction of any current indicated by interposing a battery of three Leclanché cells, connected in series, if the direction of the current is from the return to the pipe, or by interposing one Leclanché cell if the direction of the current is from the pipe to the return.

In order to provide a continuous indication that the condition (i.) is complied with, the company shall place in a conspicuous position a suitable, properly connected, and correctly marked current indicator, and shall keep it connected during the whole time that the line is charged.

The owner of any such pipe may require the company to permit him at reasonable times and intervals to ascertain by test that the conditions specified (ii.) are complied with as regards his pipe.

When the return is partly or entirely uninsulated, *a continuous record shall be kept by the company of the difference of potential during the working of the tramway between the points of the uninsulated return furthest from and nearest to the generating station. If at any time such difference of potential exceeds the limit of 7 volts, the company shall take immediate steps to reduce it below that limit.*

The current density in the rails shall not exceed 9 amperes per square inch of the cross-sectional area.

The insulation of the line and of the return when insulated, and of all feeders and other conductors, shall be so maintained that the leakage current shall not exceed one-hundredth of an ampere per mile of tramway. The leakage current shall be ascertained daily before or after the hours of running when the line is fully charged. If at any time it should be found that the leakage current exceeds *one-half* of an ampere per mile of tramway, the leak shall be localised and removed as soon as practicable, and the running of the cars shall be stopped unless the leak is *localised and removed within 24 hours.*

The insulation resistance of all continuously insulated cables used for lines, for insulated returns, for feeders, or for other purposes, and laid below the surface of the ground, shall not be permitted to fall below the equivalent of 10 megohms for a length of one mile.

RAILLESS ELECTRIC TRACTION.

Where the traffic conditions do not justify the construction of an electric tramway, but where electric power is available, railless traction provides an alternative to the motor omnibus. Two overhead conductors are provided, as lead and return, and the vehicles carry trolley poles with under-running trolleys collecting the current from the conductors. These trolleys permit the vehicle to deviate at least 15 ft. from the centre-line on either side, so that they can pass other vehicles; on meeting a similar vehicle moving in the opposite direction the trolleys of one must be removed from the conductors whilst the other passes. Railless tramcars compared with motor omnibuses have higher acceleration, lower working costs, longer life, and greater elasticity as regards the number of passengers carried, while they give a more reliable service and a greater annual mileage, and can climb hills with greater ease. The cost of maintenance is about 1*d.* per car mile (exclusive of tyre renewals, which amount to about 1*d.* also), and the consumption of energy is about 1 kw.-hr per car mile. The life of a trolley omnibus is ten to fifteen years, *i.e.* about double that of a motor omnibus. The vehicle costs about 2,000*l.*, and the overhead construction about 2,700*l.* a mile. The seating capacity of a single-deck car is from 28 to 36, and the speed 16 miles per hour. Double-deck cars have been built to carry 59 passengers. Many installations of this class are at work in this country and abroad.

Mr. E. M. Munro states that the approximate cost of energy per passenger mile can be ascertained from the following data :—

Type of Car.	Energy per Car Mile.	Average Passengers carried per Mile on 38% Seats.	Cost of Energy per Car Mile at 1½d. kw.h.	Average Speed m.p.h.	Cost of Energy per Passenger Mile.
Railless single decker .	1·00 kw.h.	11	1·5*d.*	8·0	0·136*d.*
„ double decker	1·66 kw.h.	20	2·49*d.*	8·0	0·125*d.*
Tramcar . . .	2·00 kw.h.	24	3·0*d.*	7·5	0·125*d.*
Petrol Omnibus (petrol) .	0·166 gals.	13	4·359*d.*	8·0	0·335*d.*

The above results are averaged from a number of examples and types examined for this purpose.

The following municipalities operate railless traction vehicles to a greater or less extent:

Aberdare U.D.C., Birmingham, Bradford, Halifax, Ipswich, Keighley, Leeds, Ramsbottom U.D.C., Rotherham, Tees-side Railless Traction Board, West Hartlepool, Wolverhampton, York.

Industrial Electric Trucks.

For moving material about railway stations, factory premises, etc., electric battery trucks have been widely adopted, capable of carrying up to 5,000 lbs. and running at speeds up to 8 miles per hour; the net weight of the trucks is 1,600 to 2,500 lbs., and the mileage per charge 15 to 25 miles. In a railway warehouse 11 tractors and 600 trailers handled 130,000 tons per annum at an average cost of 15·1*d.* per ton. (*R. J. Mitchell.*)

Electric Battery Vehicles.

Useful data on electric battery vehicles was given by Mr. C. W. Marshall at the I.M.E.A. Convention in Glasgow, 1926, based on the experience of the Glasgow Corporation Electricity Department since 1913 with almost every available type of vehicle. The present position is that the lead battery is in favour, due in a great part to the fact that it is much cheaper in initial cost and at the same time gives service at least as good as that obtained from the alkaline battery. The question of the relative merit of thin and thick plate lead batteries is still an open one. The thin plate battery lasts only 12 to 15 months and costs about 60 per cent. of the price of the thick plate battery, which lasts 30 to 36 months. It is, however, possible to get a much greater capacity for a given weight and volume with the thin plate battery, and so in some cases the vehicle becomes much more useful. For example, vehicles in the service of the Glasgow Corporation Cleansing Department which could do only one shift on refuse collection when fitted with thick plate batteries can do two shifts with thin plate. Alkaline batteries cost from 2 to 4 times as much as the best lead batteries. Although they last at least 5 or 6 years under hard service conditions, and 8 or 10 years under easier conditions, their low watt-hour efficiency and high internal resistance counteract the long life to some extent. Battery data is summarised in Table I.

TABLE I.—BATTERY DATA FOR ELECTRIC VEHICLES.

Type of Battery	Alkaline.	Lead.	
		Thin Plate.	Thick Plate.
Watt-hour efficiency in per cent.	59	75	75
Watt-hours per cubic inch	0·74	0·8	0·6
„ „ „ pound	15	12	9
Approx. initial cost in £ per kw.h.	30	4	8
Life in years	6–8	1	3
Life in cycles of charge and discharge	1800–2400	300	900

The capital and operating costs of plain electric lorries of the very best quality of load capacities of 0·5 to 5 tons are given in Table II. The total distance covered is taken to be 10,000 miles per annum and the cost of electrical energy to be 0·75*d.* per unit. The daily distance covered by a battery vehicle should not exceed 35–45 miles.

Mr. Marshall also gives the following data concerning the costs of competing transport systems. For a horse-drawn vehicle, the annual operating costs work out at 239*l.*, with an average cost per vehicle mile of 10·7*d.* A comparison between petrol, steam, and electric vehicles can be obtained from Table III.

TABLE II.—FIRST COSTS AND RUNNING COSTS OF ELECTRIC LORRIES.

RANSOMES' ELECTRIC TROLLEY BUSES.

(*Ransomes, Sims & Jefferies, Ltd., Ipswich.*)

One of the leading makes of railless electric vehicles is the Ransomes' Electric Trolley Bus, made by Ransomes, Sims & Jefferies, Ltd., of Ipswich, who have designed two standard types of 4-wheel chassis.

The Type C Chassis is constructed primarily for the purpose of obtaining the lowest possible floor line and can be supplied as (1) a single deck saloon bus with either a front or rear entrance or both, or with a central entrance; (2) with an open or covered in double deck body, in which case the rear or loading platform would be exceptionally low. The motor has been placed above the fore axle in the position occupied by the engine in a petrol-driven vehicle.

Type D.—This design enables the entrance to be placed in front of the fore axle and gives the best possible arrangement for a one-man operated bus. It is equally suitable for use with an

additional rear entrance if a conductor is employed. The motor in this type is fitted about midway between the front and rear axles.

The back axle in both types has been specially designed to transmit the heavy power developed by the motor under the most severe conditions of overloading and steep gradients. The standard practice is to fit a single traction-type motor, but, a twin motor unit suitable for series parallel control can also be provided. The motor is of the ventilated type, special air entry and air outflow cowls being provided at each end in order to prevent splashings from the road surface entering the motor case. The motor complies with the British Standard Specification for Traction Motors in regard to rating, temperature rise, etc., and is designed to give rapid acceleration. Each rear wheel is fitted with two powerful independent brakes, each working on separate drums, and operated by foot pedal and ratchet pattern hand levers respectively. When desired, pedal-operated air brakes may be supplied, or four wheel brakes can be fitted. The steering gear is so designed that the effort required for steering is reduced to a minimum. Either pneumatic or solid tyres can be supplied. The springing of the chassis has received very careful attention and an extremely easy riding bus has been developed.

*Type D.*6.—The most recent development in trolley bus design is Ransomes' Type D.6, a 6-wheeler with double deck and top cover, the wheels all being fitted with giant pneumatic tyres. Several special features are incorporated in the design.

These vehicles are believed to be the first to be fitted with no fewer than twenty brake shoes. There is an independent brake on each of the six wheels, actuated by means of Westinghouse air system. These same shoes can be operated at will by means of the ordinary foot pedal placed in the driver's cab. The arrangement is such that, if required, the air pressure can be supplemented by foot pressure from the driver. There is also an entirely independent set of brakes on each of the four rear wheels, operated by means of a hand lever. This hand lever is electrically connected with the controller circuit, so that it is impossible for the man to operate his controller pedal with the hand brake in the ' on ' position. With such a braking system as is outlined above one would naturally expect exceptional performances, and as a matter of fact the stopping distances of the trolley buses when fully loaded with passengers are equivalent to those of the best private cars.

A very important item in the construction of the chassis is the adoption of the Thornycroft patent bogie. This offers a number of very important advantages, the greatest of which is, perhaps, the fact that the torque reactions due to acceleration and braking forces are taken care of without the need for introducing rigid torque rods, which at their best leave very much to be desired.

Another important feature of the Thornycroft suspension system is that the load on each of the bogie axles is exactly compensated so that under no condition can either rear axle take more than half the load which is on the bogie.

A special, and it is believed, a quite novel innovation is embodied in these vehicles, namely, a third differential in the transmission system. In the same way that the Thornycroft patent bogie system equalises the dead weight to be borne by each of the rear axles, so the third differential equalises the drive between all four rear wheels, each of which is free to roll freely on the road at a speed which may differ from any of the others due to varying diameters of the tyres, which latter of course depend on the wear of the tread and the comparative inflation pressure. Although there may be something to be said against the use of a third differential for vehicles which have to operate under war conditions (in which case excessive tyre wear is not an important factor) the manufacturers consider that the fitting of a third differential will materially increase the life of the tyre, reduce considerably the wear and tear, and tend to reduce power consumption under service conditions.

The chassis is fitted with a twin motor of 60–65 h.p., the two armatures being mounted in a casing which is common to both. This arrangement has been fitted so as to give all the advantages which come from series-parallel control, and tests have proved the great advantages gained by adopting this form of control in such large vehicles as those under consideration. The acceleration is smooth but rapid, and nothing short of exceptional gradients of 1 in 11 can be negotiated at speeds of 16 m.p.h. The electric motors are made by Ransomes, Sims & Jefferies, Ltd., the control gear being supplied by the Electro Mechanical Brake Company of West Bromwich.

Special attention has been given to the driving, and controls and pedals are arranged in the most convenient positions for operation. A raked steering column is provided, and this, with its double reduction gear, gives one-hand steering.

A notable departure from usual practice is the new patented system of carrying the trolley booms on the roof of the upper saloon. Messrs. Ransomes, Sims & Jefferies consider that the orthodox method of supporting the trolley base on the roof of this class of vehicle is not sufficiently robust to provide for all the stresses which are set up under service conditions. The firm, some little time ago, took out a patent covering a new form of support for the overhead gear, which relieves the roof of all stresses and transfers them directly to the pillars, which, of course, form the main stay for the sides of the bodywork. The construction permits of the roof being made lighter than hitherto, as it has been found that the new design not only relieves the roof of stresses due to overhead trolleys, but, in addition, is sufficiently robust to greatly strengthen the roof, and thus avoid any undue ' working' of the latter due to the constant variation in loads which are transmitted from the overhead gear.

The pillars, the hoop sticks supporting the roof, and the floors are reinforced with steel flitch plates. The body is thus strengthened by means of a series of steel bands completely encircling it. This has been the firm's standard form of construction for a considerable time, and has proved to have all the advantages of the complete steel or complete wood bodies, without many of their disadvantages.

Petrol-Electric Lorries.

In the petrol-electric vehicle the motive power is provided by a petrol engine, but the mechanical gear and clutch are replaced by a very flexible electric transmission. In a recent type of Stevens petrol-electric lorry of 3 tons capacity, the generator driven by the engine gives from 300 amperes to 80 volts to 230 amperes at 110 volts, and in addition to driving the vehicle it can be used to supply power for charging a battery or electric lighting, welding, etc. The electric motor is supplied through a special controller which gives forward and reverse connections with a wide range of speed variation, and when put in the neutral position enables the generator to supply electricity for external use. In the last case the generator can be given any desired characteristic—under, level, or over-compounded. A 3-ton waggon can supply three arc-welding equipments at 60 volts.

Storage Battery Locomotives.

The development of the electrification of railway termini in large cities has been retarded by the complications and expense of equipping goods yards and sidings with overhead or third rail. To meet the problem, storage battery locomotives have been designed, the storage battery being particularly well suited to improve the economy of operation where the load is of a very fluctuating nature with high peak demands but with a low average demand, as the battery is capable of discharging at very high rates for short periods of time.

Many of these storage battery locos are in service, and favourable reports are furnished by the engineers operating them. The advantages in goods yards shunting service are as follows:

(1) The locos can be operated wherever there are rails and in buildings or yards where any form of smoke or exhaust gas is objectionable.

(2) A storage battery can deliver power at very high rates; it is capable of developing great tractive effort for acceleration, which is of particular importance in shunting.

(3) Construction and operation are simple. A storage battery contains no moving parts and requires little attention.

(4) Economies will be effected in the total investment and in the cost of operation compared with that of steam locos.

The largest storage battery locomotive in the world was recently built by the General Electric Company at their Erie Works for shunting service by the Chicago and Northwestern Railways in Chicago. It is equipped with a battery of 120 Exide-Ironclad type FL-31 cells, and in addition it has an auxiliary gas engine and generator, and can operate off a third rail as a combination battery and trolley locomotive.

The power that can be developed by this locomotive at 25 per cent. adhesion is 55,000 lbs. tractive effort at over four miles per hour, which is equivalent to 600 horse-power at the wheel rim. A train of sixty 80-ton cars could be started by such a locomotive and brought up to a speed of 8 or 10 miles an hour.

Data concerning this 110-ton storage battery locomotive are as follows:

Locomotive complete	237,000 lb.	Speed at one-hour rating	10 m.p.h.
Mechanical equipment	100,700 lb.	Tractive effort 30 per cent. co-efficient of adhesion	66,000 lb.
Battery	78,960 lb.	Maximum speed	30 m.p.h.
Motor	29,800 lb.	Time motors will carry maximum tractive effort	8 mins.
Engine and generator	7,850 lb.	Ampere-hour capacity at 6-hour rate	2,700
Radiator and fan	3,500 lb.	Average volts at 6-hour rate	228·0
Control	9,150 lb.	Kw.-hour capacity at 6-hour rate	616
Brakes	5,640 lb.	Max. discharge rate in amperes.	6,500
Heater	1,400 lb.	Max kw. discharge rate	846
Length overall	52 ft. 0 in.	Approx. weight of battery	78,960 lb.
Wheel base	39 ft. 0 in.	Approx. floor space	200 sq. ft.
Rigid wheel base	8 ft. 0 in.	Approx. over-all height of battery	38 in.
Height	14 ft. 8 in.		
Width	10 ft. 0 in.		
Tractive effort one hr. capacity	20,000 lb.		

Charging Battery Vehicles.

Battery vehicles are well adapted for charging during the night hours, and specially low tariffs for this purpose are now offered in many districts. A standard Charging Plug and Socket is specified in B.E.S.A. Report, No. 74—1929.

ROADS AND STREETS.

In view of the important changes in highway administration, which came into force from April 1, 1930, the related statistical matter in this section has been only slightly revised. As it stands, it may be considered to mark the end of a short era, during which the main objectives have been to effect such a classification of roads as really corresponds to the distribution of traffic, and to make the roads in every class good enough for the purposes which they serve.

This has, though not yet completely, been done, by new construction of arterial and by-pass roads, allowing of the establishment of a normal first class of main roads; by transfers, aided by grants for reconstruction; by grants for the improvement of various classes, and by annual grants for ordinary maintenance.

ADMINISTRATION.

UP TO APRIL 1, 1930.

Road administration in the United Kingdom is carried out by individual local authorities, each of which appoints its own road surveyor. The financial arrangements are, however, such as to lead to relations between the council of a county and those of districts in the same administrative county, as regards some proportion of the roads, the extent to which this has occurred depending partly upon the circumstances of the area and partly upon the policy of the councils concerned.

Recent Grants.—For distribution of grants, see p. 721.

Highway Authorities.

In all three countries the county councils are concerned with the maintenance of roads, but the arrangements differ, since there are no district councils in Scotland, while the relations between the county councils and the district councils are not the same in Ireland as they are in England and Wales. Subject to the financial modifications resulting from Government grants and the general supervision exercised by the Ministry of Transport in respect of the use of this money, the basis of highway administration is as follows:

England and Wales.—With some exceptions, applying to only a small mileage, the roads are maintained by the various authorities as follows. In cities and county boroughs all the public roads are maintained by the corporation or the borough council. In non-county boroughs and urban districts the urban council usually maintains all the roads, but the county council pays a considerable part of the cost of maintenance of such 'main' roads as pass through the area in question; and sometimes they are directly maintained by the county. With respect to rural roads it may be regarded as the normal arrangement for the more important roads, having been declared to be 'main' roads, to be maintained directly by the county council, and to be in charge of the county surveyor, while the other roads are maintained by the district councils, each council having its own surveyor. In effect there are wide differences, for the proportion of county roads to the whole may be very small or very large, the average being about 24 per cent.

In other cases the 'main' roads are maintained by the district councils under a contract with the county council; or the most important of the district roads are the subject of grants made by the county council. Since the roads directly maintained by the county must be technically 'main' roads, it follows that in counties having a large proportion of the total mileage under county management many technically 'main' roads are roads which are in fact 'secondary' in character or even less important; and conversely, there are many counties in which the main roads in fact are classed as 'assisted roads,' or are, some of them, district roads maintained at the cost of the local ratepayers.

Ireland.—The roads in Ireland are divided into 'main roads' and 'district roads.' The latter are maintained by, and at the cost of, the urban and rural districts in which they are situated, while the cost of main roads is equally divided between the district and the county. The sums for the maintenance of both classes of roads have first to be voted by the district councils, the power of the county council being almost entirely one of veto.

Administrative arrangements in the Free State are undergoing modification under the new conditions.

Scotland.—In Scotland there are no rural district councils. The urban roads within the burghs are maintained by the burgh councils and the rest of the roads by the county councils. Small counties, such as Elgin, Clackmannan, and Kinross, are each in charge of one surveyor, and Sutherland, where many of the roads are maintained by contract, has one surveyor. The larger counties are divided into districts, each in charge of a surveyor working under the district committee of the county council. Most of the counties are divided into two or three districts, but some large counties, such as Ayr, Perthshire, and Lanarkshire, into five. The mileage in a district ranges from about 120 miles in populous districts to some 500 or 600 miles in sparsely peopled districts. Each district committee of a county is composed of the county councillors representing that district. With their own officials they do all the county work for the district, and report their proceedings once a year to the county council, of which they are the component parts. In road matters the district councillors also report to the county road board, which is composed of members from each of the districts. It is recognised that the roads are better managed by persons intimately acquainted with the needs and resources of the relatively small area, and it is held that it is better to secure the services of qualified and experienced men for the direct management of the roads in each district than to employ less efficient local surveyors under a county surveyor. Midlothian is an exception to the rule in Scotland, the system of management resembling that of an English county in which a large proportion of the roads are directly maintained by the county. There are four districts, each in charge of a district surveyor, the whole being controlled by a county surveyor, through whom the reports from each district are made to the county road board. The traffic in this area is considerable and of a severe character.

Great Britain.—The Ministry of Transport contributes 50 per cent. towards the costs of maintenance of Class I. roads, and 33⅓ per cent. towards the costs of maintenance of Class II. roads; sums are also allotted in aid of the maintenance of unclassified roads of a purely rural character. In 1926 the mileage of these rural roads scheduled for grants was nearly 36,000, the 1926–1927 total being not far short of 41,000, and the March 1928 total, 55,000. This, at present, purely financial classification is independent of that under which 'main' roads are distinguished from roads not directly maintained by county councils. Since, however, the basis of it is the amount or severity of traffic, it is likely to prevail, the allotment of grants for unclassified rural roads creating in effect a third class. The result, if logical, will be four classes, unless the aided rural roads be added to Class II.

After April 1, 1930, the grants for Class I. and Class II. roads will probably be, respectively, 60 and 50 per cent.; while metropolitan and county boroughs will receive 'block' grants, based on the same percentages of recent expenditure. County councils will also receive block grants, available in aid of the maintenance of 'scheduled' roads.

For mileages, see pp. 716, 720, 722, 744.

The Local Government Act, 1929.

(Came into force April 1, 1930.)

The Act constitutes the county council, the highway authority in respect of all repairable roads in rural districts, and all present and future classified roads in urban districts and non-county boroughs with populations not exceeding 20,000. The county councils will have all functions hitherto exercised by the rural district councils under the Highway Acts, 1835 to 1885, and rural district councils will cease to be highway authorities.

County Roads.—The county council will have, with respect to the roads for which it becomes the highway authority, the like functions as with respect to main roads, enactments relating to which shall have effect as if for references therein to main roads there were substituted references to county roads.

Except in respect of urban claimed roads, every county road, its materials and drains, shall vest in the county council.

Classified Roads.—The term 'classified roads' will include roads in any class declared by the Minister of Transport to be not inferior to Class I. or II. for the purposes of the Act.

An Order creating a new urban district may provide that the county council shall continue to maintain the unclassified roads, the urban council making payment to the county council.

Transfer of other Functions.—As regards powers exercised in rural districts by the county council under the Private Streets Works Act of 1892 and sect. 150 of the Public Health Act, 1875, the county surveyor when preparing his specification shall, if and so far as the works include sewers, consult the rural district council.

Obstructions on footpaths caused by the placing of building materials, &c., will be dealt with by the county council.

Sections 21 and 22 of the Public Health Act, 1925, relating to water flowing over or soil falling on to a footpath, will be administered in rural districts exclusively by the county council; in urban districts, in respect of county roads, either by the county or the urban council.

In rural districts and, in respect of county roads in urban districts, the county council, or the district council, with the consent of the county council, may deal with street refuges, cabmen's shelters, trees in streets, and public conveniences and lavatories.

Powers Delegated: Powers Claimed: Appeals.

County councils are authorised and, unless they are able to satisfy the Minister of Transport that such a course is undesirable, are required to delegate to the rural district councils the maintenance and repair of unclassified roads. Rural district councils wishing to avail themselves of those powers must make application within three months of the commencement of the Act, the application relating to the following: all unclassified roads other than county bridges; all or any of the classified roads in the district; all or any of the county bridges. In respect of the second and third the county council will have 'unfettered discretion' to grant or refuse the application. In respect of unclassified roads, the county council must grant the application, unless satisfied that it is undesirable to do so, on grounds of efficiency and economy in highway administration.

Delegation of Powers.—Before October 1, 1929, councils had to inform the Minister of Transport how applications for delegation of powers had been dealt with and, as regards unclassified roads, the grounds of refusal had to be specified. District councils had a month in which to appeal against refusal to the Minister of Transport, who might direct the county council to grant the application. Appeals that shall have failed may be renewed every five years, or at any other time if with the consent of the Minister. A county council having delegated its powers with respect to roads or bridges may withdraw such delegation, subject to appeal by the district council to the Minister in respect of unclassified roads.

Control of Delegated Functions.—In respect of delegated powers, the district council will become agents for the county council, the execution of works, and the expenditure to be approved by the latter, who will also have some control over *personnel* and the terms of contracts. Works must be completed to the satisfaction of the county council who, in the event of non-compliance with their requirements, may themselves do what is necessary.

Urban Districts.—In regard to the right of urban districts of over 20,000 inhabitants to maintain their classified roads, those roads will all vest in the urban council, as if they were ordinary roads so vested. The cost of maintenance, repair, and reasonable improvement of those claimed classified roads will be borne by the county council, to whom detailed estimates must be presented every year. Approval of the estimates must not be unreasonably withheld, disputes as to estimates or the execution of works being settled by the Minister of Transport.

County councils will contribute towards the cost of improvements of classified roads generally, disputes being referred to the Minister of Transport, who will consider the purpose of the improvement for through traffic, for local traffic, or as a 'town' improvement.

The right of urban districts of less than 20,000 inhabitants to maintain previously 'claimed' main roads will lapse. An urban district council may, with the consent of the county council, or with an overruling decision of the Minister of Transport, relinquish the maintenance of a county road.

The clauses respecting classified roads in metropolitan and county boroughs mainly relate to grants.

Sources of Information.—The effects of the Act are explained, and action which must or may be taken by the local authorities on or before April 1, 1930, indicated, in a Memorandum issued by the Ministers of Health and Transport.

The significance of the Act, from the point of view of highway authorities, was discussed in a paper by Mr. W. J. Hadfield, at a joint meeting of the Yorkshire and the North-Western Districts of the Institution of Municipal and County Engineers, April 13, 1929.

The Local Government (Scotland) Act, 1929.

The Act constitutes the county council the highway authority for the whole county, district committees and standing joint committees ceasing to exist. The term 'county' is defined as including 'small burghs'—that is, burghs of less than 20,000 inhabitants. Excluding 'large burghs,' of 20,000 or more inhabitants, there will be a uniform road rate over the whole county.

Present and future classified roads in 'small burghs' will come under the jurisdiction of the county councils.

Contributions in lieu of rates, and the Government contribution towards the cost of maintaining roads (Act of 1889) will be discontinued.

The percentage grants for classified roads' maintenance will continue, but unclassified roads will be subject to a block grant, stabilised for a period of three years, based on the grant made for the year 1928–1929 with the addition of $\frac{1}{91}$ of 3,000,000*l.*

Delegation of Powers.—A county council may delegate the maintenance of classified roads within a 'small burgh' to the town council of that burgh.

Resulting Changes.—The number of administrative counties will be reduced from 33 to 31, and 98 district committees will be abolished. The classified roads of 173 'small burghs' will come under the control of the county councils, about 260 miles in Class I. and 84 miles in Class II.

The county councils must submit schemes for the administration of highways to the Secretary of State, on or before March 31, 1930, when it will be known which of the existing arrangements (see 'Scotland' on p. 712) is likely to predominate.

Ministry of Transport: Roads Department.

Constituted under the Act of 1919, the Ministry of Transport took over the powers and duties of Government departments with respect to (*a*) railways; (*b*) light railways; (*c*) tramways; (*d*) canals, waterways, and inland navigations; (*e*) roads, bridges, ferries, and vehicles and traffic thereon; (*f*) harbours, docks, and piers. The powers and duties of the Road Board were also transferred to the new Ministry. These include: powers to acquire land for the making of new roads and for road improvements (Act of 1909), and the duty of allotting grants to local authorities for the purpose of road improvement. These functions are carried out by the Roads Department of the Ministry, which is 'charged with dealing in the ordinary course of departmental business with road construction, improvement, maintenance, and development.' The Ministry may, by agreement with the local authority, defray half the salary and establishment charges of the engineer or surveyor to a local authority.

The Ministry is also charged with the allotment of grants for road maintenance, acts in an advisory capacity as regards both financial and technical matters, and directs the general policy in the expenditure of the large sums allotted recently for special works intended to reduce unemployment.

LEGAL POINTS FOR ROAD ENGINEERS.

The same principles of law govern all highways, whether carriage roads, bridle paths, or footpaths. The widths of some roads have been fixed by legal enactments; in England, for instance, by awards under Inclosure Acts, and in Scotland a minimum width, with powers to take a further width was prescribed by the Roads and Bridges Act of 1878. The width of a highway may be greater than that set out in an award, but *prima facie* it is not. The width has often been determined by dedication, and in some cases the dedication was recent and the intended width may be clearly inferred; but in many cases the act of dedication is presumed, or the road is a legacy from ancient times. In such cases the usual presumptions are that the abutting owner of the soil is the owner of the soil to the middle line of the road, and that the right of public passage extends from fence to fence. Road engineers should note, however—when roads require widening—that there may have been recent encroachment and that a strip beyond the fence may be really a part of the highway. There have been many such encroachments. The principle 'once a highway always a highway' should not be lost sight of. The actual width of the highway and the nature and extent of the facility to which the public has a right may depend upon the manner in which, and the extent to which, the public has used the road and its margins as well as upon the extent to which and the manner in which the owner of the soil or his tenant has exercised rights of ownership, or has done things which tend to show that the dedication of the road is subject to reservations. It is important to note that a wayside ditch, though usually a part of the highway, may be outside the highway, and, especially when a road has been set out under an award, it should not be too readily concluded that a ditch lying beyond the width of the strip awarded is a part of the highway. The highway usually extends to a depth such as may be necessary for the proper maintenance of the road and to a height required for the passage of laden vehicles. The obstructions permitted on a highway are those which are authorised by Acts of Parliament, such as telegraph posts placed by the Postmaster-General, and pipes laid by water and gas companies in defined areas. No individual or society has the right to place any post or other obstruction on the highway, except the owner of the soil where he can clearly establish

a claim to such a right. Failing this, the presumption is that he cannot place on the highway anything which amounts to an obstruction of public passage in its widest interpretation. The highway authority may erect direction posts, and, presumably, posts for cognate purposes, but it seems that such an authority may not erect lamp-posts unless they have powers as a lighting authority, even if the lamps are intended to facilitate the use of the road by the public. The highway authority has no powers enabling it to place posts or other obstructions upon the highway in the interests of certain classes of users of the road. The tendency is, however, for local authorities to go beyond their powers, and road surveyors will probably be required to carry out many works near the border line of those powers. Generally, as regards the placing of pipes, conduits, or wires along or across the highway, the persons doing so without statutory authority are likely to come into conflict with the public, or the owner of the soil, or both.

Width of Carriageway.—There is usually a presumption that the highway is dedicated in part as a carriageway, in part as footways, and grass margins which are regarded as occasional footways and rides, and in part as ditches, banks, and other enduring features necessary to the maintenance of the highway as established by use. It may, therefore, be desirable in some cases to obtain the formal consent of the owner of the soil to any radical alterations, such as the filling in of ditches. As regards trees and hedges it is important to distinguish between the powers of the highway authority as regards actual obstruction, and their further powers relating to the lopping of trees and cutting of hedges which injuriously affect the road, these powers being restricted to the months of October to March inclusive. Similar powers, not restricted to any season and applying to cases in which the tree or hedge obstructs the view of drivers of vehicles, are conferred by Clause 23 of the Public Health Act, 1925, while cases in which trees or hedges obstruct the view of drivers but do not overhang the highway may be dealt with under section 4 of the Roads Improvement Act, 1925.

The Highway Authority.—Must maintain the road in a condition fit for the passage of the public; may enforce the lopping of trees and cutting of hedges in the manner already indicated; may recover damages for substantial injuries caused by 'extraordinary traffic'; may enforce the removal of obstructions from the highway; may enforce by-laws such as those regulating the locking of wheels and the use of skidpans, and the widths of tyres in proportion to the loads carried.

The Public.—The public rights affecting the maintenance of roads include—the recovery of damages caused by 'misfeasance' on the part of the local authority, such as the placing of heaps of stone within the limits of the highway or the fixing of manholes, in such a manner as to cause accidents.

Any member of the public who finds on a highway an object which is in fact an obstruction or a nuisance may take proceedings against the person responsible for its presence, unless it is placed there under statutory authority.

Ownership.—In certain cases the highway authority becomes owner of the soil to a greater or less extent. In boroughs and urban districts, streets taken over by the local authority are vested in that authority. In rural districts 'a main road and the materials thereof and all drains belonging thereto' vest in the county council, but this does not constitute the council owners of the soil or give them powers over roadside wastes beyond those proper to their duties as the guardians of the public right of passage. As regards new roads made by the Ministry of Transport, it has the same powers and duties as those of a county council (except that of levying rates); and it is clear that if the road is on land which the Ministry has bought outright, with powers 'to sell, lease and manage' it, the Ministry becomes owner of the soil; and the Development Act does not seem to contemplate the acquisition by the Ministry of limited rights. In rural districts, highways other than main roads are vested in the owners of the soil.

Extraordinary Traffic.—It has been held that, in the circumstances of a particular case, the haulage of 100 tons a week for five weeks was extraordinary traffic.

Heavy Vehicles on Bridges.—The owner of a bridge may prohibit the crossing of the bridge by a vehicle weighing more than 3 tons, but subject to confirmation, or an increase in the limit, by an umpire or arbitrator.

Bridges as 'Streets.'—By a legal precedent of 1926 (Mr. Justice Romer), a bridge may become a street within the meaning of the Public Health Act, 1875.

The Roads Improvement Act, 1925.

A highway authority may impose restrictions or enforce changes in respect of the use of land at or near a turning or a bend in a highway, in order to prevent danger arising from the obstruction of the view of persons using the highway. Relates especially to the height and character of a wall or hedge. Provision is made for the payment, by the highway authority, of the cost of alterations and compensation for losses sustained as the direct result of those alterations.

A highway authority may prescribe building lines on either or both sides of a highway.

On classified roads the approval of the Minister of Transport is required. Building lines prescribed by urban authorities must be approved by the county council. County councils must notify the local council of building lines prescribed for main roads, and plans must be open to inspection by the public. Compensation for injury to property may be claimed.

The Public Health Act, 1925.

Highway authorities are empowered to lop trees which overhang highways; in the case of a main road the power is exercised by the county council. Appeal may be made to the Petty Sessional Court.

Local authorities are empowered to prescribe improvement lines for widening streets. Compensation may be claimed. In respect of main roads county councils are given the same powers.

See the texts of the Acts, or Mr. E. J. Stead's presidential address to the Association of Somerset Engineers ('*The Surveyor*,' January 1, 1926).

Bus-Mileage Tax.—Under the Act of 1920, the local authority may, if the Minister of Transport approve, impose a tax of ½*d.* per bus mile on regular services.

A local authority may apply to the Ministry of Transport for an order prohibiting or restricting the use of heavy motor vehicles on roads which are unsuitable for them.

Arbitration.

The settlement of disputes by arbitration is often more satisfactory than by recourse to the Courts.

The Bridges Act, 1929.

The Bridges Act, 1929, applies only to bridges which carry public carriage roads and are not maintainable by highway authorities. In most cases, the owners of such bridges have hitherto not been bound to maintain the bridge in a condition sufficient for traffic other than that of the time when the bridge was originally built.

The Act enables a highway authority, by agreement with the owner, to take over the property in any bridge to which the Act applies, or, the bridge remaining vested in the present owner, to contribute towards the cost of its maintenance, improvement, or reconstruction. In cases in which such an agreement is not reached, or a definite order of the Minister of Transport is held to be more advantageous, the owner, or the highway authority, may apply to the Minister for an order.

Such an order may require the execution of any necessary works of improvement or reconstruction, or may determine who shall be responsible for the future maintenance of the road which the bridge carries.

Subject to specified exceptions, the order may transfer the property in the bridge to a highway authority, or determine that the authority shall be responsible for the maintenance of the structure.

An agreement or an order may relate to the transfer to the highway authority of responsibility for the maintenance of the road on the bridge and its approaches, without transfer of property in the bridge or in the road over it, or of responsibility for maintenance of the bridge itself.

The Act is intended to provide for contributions by the owner, in respect of costs of maintenance, improvement and reconstruction, to the extent of his present liability. In the case of an Order made by the Minister, provision is made for the settlement by arbitration of disagreement as to the amount to be contributed by the owner. The remainder of the cost will be borne by the highway authority.

In cases in which the highway authority assumes an additional liability in respect of improvement or construction, the Minister is prepared, in approved cases, to make grants up to 75 per cent. of the approved net cost falling on the highway authority.

In respect of maintenance costs, grants normal for the class of road will be applicable.

HIGHWAY STATISTICS.

Road Mileage in Relation to Population and Area.

Road Mileage, per square mile.—Norway, 0·17; Spain, 0·174; Sweden, 0·205; New South Wales, 0·223; Hungary, 0·253; Switzerland, 0·465; Austria, 0·641; United States Rural Roads—all rural roads, nearly 1·00; surfaced roads, including sand-clay, 0·175; not including sand-clay, but more than half the mileage of gravel, 0·151; macadam and durable materials, 0·056; Italy, 0·782; Canada, 0·014; Province of Quebec, rural roads (31,000 miles), not including trails and roads in remote colonisation districts, 0·044; Peru, 0·013; Brazil, about 0·003; Denmark, 1·724; Japan, 1·743; France, 1·750; Ireland, 1·755. *Class I., or First-class Roads*; miles per sq. mile: England and Wales, 2·62; Scotland, 0·796; Great Britain, 1·98; Bulgaria, 0·314 (State roads, 0·125; communal roads, 0·188).

[To reduce to km. per sq. km., multiply by $\frac{87}{140}$, or 0·6214.]

Persons per Mile of Road: Counties (based on mileages, March 31, 1927, and census, 1921).—*Eleven*, below 61; Radnor 23, Montgomery 32, Cardigan 44, Merioneth 48, Brecon 54, Hereford 56, Devon 57, Westmoreland 57, Rutland 58, Pembroke 60, Norfolk 60. *Sixteen*, below 90; Lincolnshire, Holland, 67; Anglesey 70, Shropshire 70, Lincolnshire, Kesteven, 71; Cornwall 73, East Riding of Yorkshire 76, Carmarthen 77, Lincolnshire, Lindsey, 78; Oxfordshire 79, Denbigh 81, Suffolk, West, 83; Somerset 85, Cumberland 86, Suffolk, East, 87; Wiltshire 87, North

Riding of Yorkshire 89. *Twelve*, below 131; Gloucestershire 93, Huntingdon 97, Dorset 98, Carnarvon 101, Hampshire 105, Flint 107, Northamptonshire 114, Berkshire 118, Isle of Ely 120, Leicestershire 124, Buckinghamshire 130, Northumberland 130. *Eight*, below 200; Worcestershire 139, Sussex, West 143; Warwickshire 145, Sussex, East 151; Cambridgeshire 153, Huntingdonshire 194, Bedfordshire 199, Nottinghamshire 199. *Nine*, 200 to 300; Staffordshire 201, Derbyshire 209, Monmouthshire 217, Cheshire 223, Soke of Peterborough 223, Isle of Wight 230, Kent 230, Essex 241, Yorkshire, West Riding, 260. *Five*, over 300; Surrey 324, Lancashire 384, Durham 424, Glamorgan 450, Middlesex 927.

Population per Mile of Road.—New South Wales, 24·6; United States, whole population and rural roads only, 39·3; surfaced roads, 224; Denmark, 75·5; France, 108·0; Norway, 130; Sweden, 154·4; Japan, 210; Ireland, about 90; Italy, 451; Canada, 169; Province of Quebec, rural roads, whole population, 76; Brazil, about 3,800; Peru, about 1,400; England and Wales, 248; Scotland, 194; Great Britain, 240; Austria, 385; Bulgaria, 460; Switzerland, 504; Spain, 575·8; Hungary, 655; Nova Scotia, 1924, a mile to every seven families.

[To reduce to pop. per km., multiply by $\frac{87}{140}$, or 0·6214.]

Per Mile of Road.—Population—Acres; Bridgewater, 1214—71; Middleton, 1051—170; Burnley, 944—42; Huddersfield, 787—85; Blackburn, 772—47; Bridport, 758—87; Rochester, 917—81; Belper, U.D., 76—20; Bucklow, R.D., 107—64; Sheffield, 1067—64; Warwick, 684—280; Cambridge, 830—87; Aylesbury, 800—21.

Mileages, 1922.—Maintained by 62 county councils, 28,177; by 243 non-county boroughs, 4,656; by 812 urban district councils, 11,870; by 661 rural district councils, 94,628.

Ireland, 1926.—About 47,000 miles, of which 8,000 miles correspond to Classes I. and II. in Great Britain.

Widths of Important Roads.

Total Widths.—Essex county council has decided that, under the Roads Improvement Act and the Public Health Act of 1925, widths shall be: for Class I. roads, 60 ft. between improvement lines and 100 ft. between building lines for residences, 80 ft. for shops; Class II. roads, 50 ft., 90 ft., and 70 ft., respectively; unclassified roads, 40 ft., 80 ft., and 60 ft., respectively. *Midland* Regional Advisory Council (committee for arterial roads and main drainage) advise: main and very important secondary arterial roads, 120 ft.; other secondary arterial roads, 80 ft.; other through routes, 65 ft.; minimum building lines, width on main arterial roads, 160 ft.

Widths including Embankments and Cuttings.—It is usual to specify that the widths of embankments and cuttings shall, for widths between improvement lines, be added to the normal widths for roads on the flat.

Worcestershire.—Highways Committee recommend as least widths: between buildings, Class I. roads, 120 ft.; Class II., 100 ft.; highway widths, Class I., 60 ft.; Class II., 50 ft. *West Riding:* Highways Committee recommends, for widenings, when necessary and economically practicable, Class A, 80 ft.; B, 60 ft.; C., 45 ft.

Carriageway Widths.—Nottinghamshire, approximate average width, by calculation, of 361 miles of tarred and other surface-treated roads (in a total of 561 miles of main roads), the treated width, 18 ft. Similarly, Isle of Ely, average treated width of tarred roads, 15 ft. 8½ ins. Berkshire, Bradfield rural district, 196 miles, approximate metalled width, by calculation, 13 ft.

Norfolk.—58 miles of roads converted 1927–1928 from water-bound macadam to tar-slag macadam, this indicating their relative importance, average width of the crust, not necessarily of the visible surface, 18 ft. 3 ins., by calculation. Warwickshire, width, by calculation, of the road crusts of reconstructed and resurfaced roads, 45¾ miles, nearly 20 ft. 6 ins.; calculation of tarred surface width, nearly 18 ft. 6 ins.

Costs of New Roads.

Recent Examples.—The Glasgow-Edinburgh main road, mostly 120 ft. wide between fences; estimated cost, 69,000*l.* per mile. Kingston by-pass road, 100 ft. between fences, 30 ft. carriageway; estimated total cost, 37,000*l.* per mile; tender for construction, 22,102*l.* per mile. Sutton by-pass road, 80 ft.; estimated total cost, 42,947*l.* per mile; tender for construction, 19,290*l.* per mile. Sheffield, widening of roads to 80 ft. and 100 ft., and entire reconstruction, 32,000*l.* per mile. Great West Road, London, 120 ft. wide between fences, 50 ft. carriageway, capable of being widened to 80 ft.; all mains crossing roads carried in subways; foundations, 12 ins. of ashes and hard core; road crust, 9 ins. of reinforced concrete; carpeting, 2 ins. of rock asphalt. Total estimated gross cost, 1,012,602*l.*, or nearly 197,000*l.* per mile. Edinburgh-Glasgow Road, 100 ft. (in parts 60 ft.) between fences, 40-ft. carriageway, two 10-ft. footpaths, some heavy excavation; about 40 miles, 24 m. new, 16 m. widenings; estimate 2,000,000*l.*, or about 50,000*l.* per mile. Whitehaven Loop Road, 41,700*l.* per mile. Tyne Coastal Road,

between Heaton and Tynemouth, estimates, 175,000*l.*; length, 4¾ miles, nearly 36,800*l.* per mile. Sutton By-pass Road, 4·64 miles, 80 ft. between fences, 30-ft. carriageway, one 8-ft. footpath; estimate, nearly 44,000*l.* per mile.

Australia.—Under the Federal Aid Highway Act: graded earth roads, 5,008 miles, 1,712*l.* per mile; sand-clay, 2,541 miles, 1,730*l.*; gravel, 9,098 miles, 2,220*l.*; water-bound macadam, 608 miles, 4,500*l.*; bituminous macadam, 841 miles, 6,630*l.*; bituminous concrete, 757 miles, 7,270*l.*; Portland cement concrete, 4,075 miles, 8,570*l.*; brick, 318 miles, 10,000*l.* per mile.

State of Victoria (1928–1929).—Construction and reconstruction; Federal Aid Roads, including bridges, 2,040*l.* per mile; State highways, 156 miles completed and 34 miles cleared and formed, average 2,863*l.* per mile. Analysis of the 156 miles: of concrete, 0·3; bituminous concrete, 2·4; bituminous macadam, 83; water-bound macadam, 27; gravel, 43 miles.

Reconstruction.—Cardiganshire, including foundations and surfacing with tar macadam, 3,167*l.* per mile. Lincolnshire (Holland), 4,000*l.* Dorset, Wimborne, and Cranbourne R.D.C., 2,791*l.* A moorland road, 5,000*l.*

Jersey, Channel Islands: scarifying, cleaning old material, and mixing with 4½ galls. of bitumen to 11½ cu. ft. of stone for bottom coat of 3½ ins. (before rolling); rolling; preparing top coat of 10 galls. of bitumen to 11½ cu. ft. of dried destructor clinker, and spreading 1½ ins. thick; rolling; costs, 7*s.* per square yard. Cost of materials and their treatment for this work, 1*l.* 10*s.* 7*d.* per ton, of which labour accounts for 10*s.* 2*d.*, bitumen and its transport charges, 8*s.* 6*d.*, granite from parish quarry, 3*s.* 2*d.*, clinker from parish destructor, 1*s.* 7½*d.*, and capital charges, 2*s.* 7*d.* Relates to 1,756 tons.

Arterial and By-Pass Roads, Examples and Data, 1924–1929.

Ordnance Maps.—A special revision of roads has been made, and the results are being embodied on the 1-in. and smaller scale sheets as they become due for reprinting.

Dartford By-Pass Road: 3½ miles; carriageway, 30 ft.; 10-ft. footpaths; total width, 60 ft.; right-of-way, 100 ft.; maximum gradient, 1 in 30.

Middlesex.—Great Cambridge Road: 10 miles; total width, 100 ft.; prepared carriageway, 24 ft.; in reserve, 24 ft.; footpaths, 6 ft.; base, 3 ins. clinker; crust, 8 ins. reinforced concrete.

Great West Road, Greater London: 8½ miles; 5½ miles done; total width, 100 ft.; carriageway, 50 ft., flanked by 25-ft. grass margins, with forest trees; 10-ft. footways; parts of grass strip, available for widening of footways if needed; base, 12 ins. hardcore and ashes; strength crusts, 9 ins. reinforced concrete; carpet, 2 ins. rock asphalt.

Staines Extension: about 3 miles; total width, 100 ft.; present carriageway, 30 ft., flanked by grass strips 29 ft. each; two 8-ft. footpaths. Crust, 8 ins. reinforced concrete.

Greater London.—Works in hand or projected: 6 miles; 80 ft.; carriageway, 30 ft.; one footpath, 10 ft.; base, 6 ins. clinker; crust, 8 ins. concrete.

8¼ miles; 80 ft. average; carriageway, 30 ft.; footpaths, 8 to 10 ft.; crusts, uncarpeted, tar-macadam and bituminous clinker, in different parts of the length.

5½ miles; 80 ft.; carriageway, 30 ft.; footpaths, 8 ft. and 8 ft. Base, hardcore and flint; top course, bituminous.

2·6 miles; 80 ft.; 30 ft.; two 7-ft. footpaths.

1·5 miles; 60 ft.; 30 ft.; two 6-ft. footpaths; base, hardcore; carpeting, 2 ins. bituminous clinker.

North Circular Road, Greater London: partly carried out, includes widenings and reconstructions; widths, 100 ft. and 60 ft. New construction, 9½ miles; widenings, 5½ miles; estimated cost, nearly 1,164,000*l.*, or 77,000*l.* per mile; including crossings of 12 railways and many streams. Examples of the work: 3½ miles of widening to 60 ft.; costs, including all expenses, about 31,000*l.* per mile; widening to 80 ft. near Ealing, 55,000*l.* per mile; near Greenford, 60,000*l.* per mile. Total length will be 26 miles.

Middlesex.—Schemes adopted in past five years for about 66 miles of new arterial roads, 47 miles of reconstruction involving considerable works, and 16 miles of improvement of existing roads; estimated cost, 7,735,000*l.*; or, averaging the classes of work, 60,000*l.* per mile.

Kingston By-Pass Road: 9·6 miles, 100 ft. wide; carriageway, clinker bottom course resting on clay; reinforced concrete 8 ins., of which the lower 6 ins. is 4½ : 2½ : 1, top 2 ins., 3 : 1½ : 1 aggregate, Thames Valley gravel.

East Ham and Barking By-Pass Road: 3¼ miles, 100 ft.; carriageway, 24 ft.; footpaths, 8 ft. and 10 ft.

Gravesend-Strood Road: 5·2 miles; 80 ft.; carriageway, 40 ft.; base, hardcore and flint; crust, bituminous clinker.

Farnham-Wrotham Road: 60 miles; 80 ft.; carriageway, 30 ft.; base, hardcore and flint; bituminous surfacing.

Birmingham-Wolverhampton : 9¾ miles; 100 ft.; carriageway, 40 ft., with two optional additions of 20 ft. each; footways 10 ft. each; base, cinders and ballast; crust, 'Tarmac.'

Bolton : 2½ miles; 70 ft.; carriageway 50 ft.; base, hand-picked stone; strength crust, 6 ins. concrete; paving, 6 ins. granite setts.

County of Durham.—New Coast Road; minimum width, 60 ft.; carriageway, 24 ft.; crust, 4 ins. tar macadam; base in cuttings and on embankments, 12 ins. punning, 4 ins. ashes. Cost, about 37,000*l.* per mile.

Glasgow : 4½ miles; two carriageways of 30 ft. each, with middle grass strip, 40 ft.; footpaths, 12 ft. each; grass margins, 8 ft. each.

Leeds Ring Road : 30 miles; 10 miles made; right-of-way, 100 ft.; initial carriageway width, 24 ft.; bottoming, 4 ins. ashes; base, 12 ins. pitching; intermediate layer, 4 ins. 'dross'; carpet, 3 ins. tar-macadam.

Liverpool, 28 miles; 120 ft.; a middle grass strip, with tramway, flanked by privet hedges; a 25-ft. carriageway on both sides of the middle strip, and 10-ft. footways outside; partly, 4½ ins. pitch-grouted macadam, without foundation; partly a 9-in. concrete strength crust paved with 4-in. cubical setts of Welsh stone. Cost about 57,000*l.* per mile.

Nottingham : 2½ miles; 70 ft.; carriageway, 20 ft.; and 2 miles; 80 ft.; carriageway, 54 ft.; base, 12 ins. of slag on 2 ins. of ashes; crust, 4 ins. tar-macadam. The works include a 3-span bridge over the Trent.

Southport : 1½ miles; 75 ft.; carriageway, 27 ft.; footpaths, 7½ ft. each; bottoming, 3 ins. clinkers; base, 9 ins. pitching; strength crust, 2½ ins. tar-macadam; carpet, 1½ in. asphaltic.

Other cases : Surrey East and West Road—nearly 5 miles; 60 ft.; carriageway, 30 ft., extendable to 40 ft.; base, 3 ins. to 6 ins. clinkers; crust, 8 ins. reinforced concrete.

Hartlepool : 1 mile 3 furlongs, and 1 mile; base, 4 ins. clinkers; intermediate layer, 9 ins. slag; crust, 4 ins. tar-macadam.

St. Austell By-Pass Road, 1¾ miles.

Essex : London-Yarmouth Road, 1¾ miles.

Mid-Glamorgan : Inter-valley road scheme: three portions of 2 miles apiece, and one portion of 1 mile; form a part of a 40-mile scheme; bottoming, ashes; base, 12 ins. of hand-picked stone; crust, 6 ins. water-bound mountain limestone; width, 30 ft.; carriageway, 20 ft.; footpath, 5 ft.

Whitby-Sandsend Road.—About 2 miles; 40 ft.; carriageway, 20 ft.; tar-grouted macadam: works include a cutting 125 ft. deep, an embankment 75 ft. high, and a bridge of 41 ft. span. Cost about 25,000*l.* per mile.

Sidcup By-Pass Road.—2½ miles; 80 ft.; carriageway, 30 ft.; two 10-ft. footways; 6 in. of clinker, 9 in. of hardcore; wearing carpet 3 in., 2-coat synthetic asphalt; cost about 50,000*l.* per mile.

Morecombe Ring Road.—2·21 miles; carriageway, 30 ft.; foundation, 14 ins. of hand-pitched rubble on ashes and clinker; cost about 41,000*l.* per mile.

London-Folkestone Road.—Maidstone to Charing; 12½ miles, 60 ft.; carriageway, 30 ft.; one 6-ft. footway; three-quarters of width is old carriageway, the remainder new, in concrete; bituminous carpet; estimated cost about 55,000*l.* per mile; estimated cost of the whole work, 400,000*l.*

Aberdulais-Resolven Road.—A county main road; 4·4 miles; 30 to 36 ft.; carriageway, 25 to 31 ft.; one 5-ft. footway; steepest gradient, 1 in 11; foundation, 8 to 12 ins. of ballast topped with mountain limestone; wearing crust, 4 ins. of tar macadam; cost about 10,000*l.* a mile.

Birmingham-Coventry Road.—Widening to 80 ft. or 60 ft., 10 miles; a spur, 6 miles to Castle Bromwich.

Newcastle-Tynemouth Road.—Nearly 4·7 miles; about 43,000*l.* per mile, or, not including the cost of four large bridges, about 31,700*l.* per mile. Half the 102 ft. width made; 30-ft. carriageway; reinforced concrete 7½ ins. at sides, 10½ ins. at centre, on flat bed of ashes; top 2 ins. blue whinstone chippings; single reinforcement.

Liverpool-Manchester Road.—27 miles; estimated to be finished by the end of 1932; 120 ft.; 40-ft. carriageway to be provided in the first instance; designed for two more (20-ft.) carriageways; and four 10-ft. footways; circuses of 240 ft. diameter at crossings of classified roads; estimated cost, 3,000,000*l.* Liverpool section, 2 miles, opened May, 1929.

Aberdeen.—Outer Ring and By-pass Road; including a bridge, 41,500*l.*

West Riding.—Barnoldswick; 70 ft.; 1¾ miles; 100,000*l.*

County Down.—Newry to Warrenpoint; 4¾ miles; estimate, 56,500*l.*

Welwyn By-Pass Road.—One mile; formation 60 ft.; large reinforced concrete bridge; 60,000*l.*

Daventry By-Pass Road.—A 20-ft. reinforced concrete carriageway; 3 in. clinker bottom course; concrete 6 ins. of 4 : 2 : 1, gravel, and 2 ins. of 3 : 1½ : 1, granite; bays 22 ft. 6 ins. × 12 ft.; reinforcement square mesh 7 lbs. per sq. yd.; one layer on excavation and surface road bed; two layers on fill; granite concrete kerbs; 1⅞ miles; nearly 21,000*l.* per mile; 60 ft. total width; maximum depth of cutting, 14 ft.; maximum height of embankment, 9 ft.

Bexley Heath By-Pass Road.—Nearly 5·7 miles; normal width, 80 ft.; carriageway, 30 ft.; concrete surface; four new bridges; about 54,000*l.* per mile; including bridges.

York Ring Road.—Six-inch reinforced concrete with (1) 4-in. tar macadam; (2) 2-in. clinker asphalt.

Inverness-Perth Road.—Completed to Blair Athol 1928. Grant of 600,000*l.* Length, 78 miles, and 25 miles of widening; carriageway, 18 ft. between 'stone haunches'; 3-in. gravel bottoming; 9-in. stone; tar-macadam carpet, 3 in.; 35 new bridges.

Construction across a bog; reinforced concrete raft 21 ft. wide and half a mile long; expansion joints 50 ft. apart; in the form of a trough, with sides 10 ins. deep and 6 ins. thick; floor 8 ins. thick, with upper and lower reinforcement.

Blackburn Arterial Road.—4¼ miles; (1) 120–100 ft.; two 30-ft. carriageways, separated by a grassed strip, two footways; (2) 60 ft.; one 30-ft. carriageway, two footways. Completed 1928, with one 20-ft. carriageway, sufficing for present traffic.

Market Weighton By-Pass Road.—In the East Riding; about 3¾ miles; estimate, 7,630*l.* per mile.

PROPOSED: 1929.

Colchester: West to East By-Pass Road.—3½ miles; estimated cost, 245,000*l.*

Porlock Hill By-Pass Road.—Steepest gradient 1 in 12; 3 miles; estimated cost, 30,000*l.*

Costs of Road Maintenance.

(Per Mile.)

ENGLAND AND WALES.

(1927–1928.)

Main Roads.—Hampshire, 654 miles; direct control 585 miles. Northamptonshire, 336 miles, 654*l.*; cost to the county, 351*l.*; directly maintained, not including improvements, 648*l.* per mile; cost to the county, 340*l.* Warwickshire, 580 miles; direct control, 512 miles, about 444*l.* Durham, 387 miles; directly maintained, 359 miles. Herefordshire, 513 miles. Somerset, rural, 924 miles (24 miles directly maintained), about 322*l.* per mile.

Classified Roads (1927–1928).—Estimated expenditure per mile, on the maintenance and repair of Class I. and Class II. roads and bridges.

Class I.—County councils; England and Wales, 17,102 miles, 539*l.*; Scotland, 5,531 miles, 302*l.*; urban and rural district councils, 790 miles, 754*l.*; county borough councils, 1,276 miles, 1,135*l.*; metropolitan borough councils, 252 miles, 2,317*l.*; Scottish burghs, 188 miles, 894*l.*

Class II.—County councils; England and Wales, 7,766 miles, 320*l.*; Scotland, 3,595 miles, 169*l.*; urban and rural district councils, 3,565 miles, 375*l.*; county borough councils, 592 miles, 938*l.*; metropolitan borough councils, 118 miles, 1,373*l.*; Scottish burghs, 50 miles, 540*l.*

All Class I., 25,139 miles, 544*l.*

All Class II., 15,686 miles, 330*l.*

Henley and Hambledon Rural District.—Omnibus routes, 9 miles, 239*l.*; Grade I. roads, 24 miles, 115*l.*; Grade II. roads, 24 miles, 75*l.*; Grade III. roads, 33 miles, including roads to single farms or houses, 2*l.* 10*s.*: total, 138 miles.

(1928–1929.)

Hampshire.—662 miles; direct control, 593 miles, the latter costing 458*l.* Holland, Lincolnshire, 218 miles, including unemployment relief works, 666*l.*

Northamptonshire.—All urban and rural main roads, 349 miles, 672*l.* per mile; 510 miles under direct control.

Somerset.—943 miles, rural, 313*l.*

Berkshire.—402 miles.

Herefordshire.—513 miles: Class I., 257½; Class II., 181; unclassified, 74½.

Sheffield.—All highways; 402 miles, 234*l.*; average of last five years, 224*l.*

OTHER COUNTRIES.

Federated Malay States.—Average, 1,474 dollars (172*l.*) per mile. 1928: 'arterial' roads, 2,600 miles, including streets in towns; average cost, 1,483 dollars, or 173*l.* per mile; most costly road, 2,004 dollars, or 233*l.* 1*s.* 6*d.* per mile.

Welland County, Canada.—About 204*l.*

Italy.—Typical costs per mile: 1st class, 4,025 lire; 2nd class, 3,220 lire; 3rd class, 2,415 lire; 4th class, 1,610 lire.

Report on the Road Fund, 1927–1928.

For full particulars as to finance, mileage, grants, road schemes, execution of works, etc., see the Annual Report on the Administration of the Road Fund, Ministry of Transport, price 1*s.* from H.M. Stationery Office, Adastral House, Kingsway, London, W.C. 2.

Finance.—(1) Road Fund receipts and payments. Receipts; issued from the Consolidated Fund (Motor Taxation Receipts), 19,665,580*l.* Total receipts, 20,348,503*l.* Payments: net payments under grants, 18,743,371*l.*; transfer to the Exchequer, 12,000,000*l.*; payment to Irish Free State, 200,000*l.* Total net payments, 31,703,364*l.*

(2) Net amount paid to Exchequer, 24,518,000*l.*; net amount paid by Exchequer to Road Fund, 19,665,580*l.*

(3) Revenue remitted to the Motor Tax Account by local authorities, 22,502,403*l.*; licences issued by Post Office, 2,335,000*l.*

Grants.—Maintenance and improvement of Class I. and Class II. roads and bridges, 9,770,092*l.* Maintenance of selected 'unclassified' roads in rural areas, 1,661,076*l.* Unemployment schemes (including trunk road reconstruction, 723,042*l.*; new bridges, 342,423*l.*; Mersey Tunnel, 1,226,821*l.*), 3,629,950*l.* Improvement works in rural areas, 1,228,180*l.* Other improvement schemes, widenings, reconstructions, bridges, etc., 1,918,215*l.* Total grants, 18,830,278*l.*

Distribution of Grants: Classified Roads.

England and Wales.—Main roads, Class I., 5,424,061*l.*; Class II., 959,126*l.* District roads; urban, Class I., 231,623*l.*; Class II., 245,312*l.*; rural, Class I., 108,405*l.*; Class II., 279,746*l.* Roads in county boroughs: Class I., 838,044*l.*; Class II., 218,021*l.* London roads: Class I., 342,194*l.*; Class II., 65,204*l.*

Scotland.—County roads: Class I., 587,107*l.*; Class II., 176,554*l.* Burgh roads: in seven larger burghs; Class I., 98,143*l.*; Class II., 10,086*l.*; in all other burghs: Class I., 158,079*l.*; Class II., 40,162*l.*

Great Britain.—Class I., 7,787,656*l.*; Class II., 1,994,211*l.*; both classes, 9,781,867*l.*

Special Grants.

Scotland.—Grants to highway authorities in areas where the highway rates are exceptionally high and long stretches of Class I. and Class II. roads run through sparsely peopled districts: up to 75 per cent.; total sum, 369,409*l.*

Rural Areas.—Towards the cost of reconditioning important roads, 1,250,000*l.* (as in two preceding years; in 1924–25, 2,250,000*l.*; in 1920–24, 1,150,000*l.*).

Grants to Counties, All Purposes.

Exceeding 400,000*l.*—Devonshire; including 139,536*l.* unemployment relief works, 489,857*l.* Essex; including 475,759*l.* maintenance Class I and Class II roads and bridges, 649,578*l.* Kent; 425,261*l.* Lancashire; including 259,616*l.* in respect of works other than maintenance and unemployment relief works, 735,618*l.* West Riding of Yorkshire, 715 525*l.*

Exceeding 200,000*l.*—Buckinghamshire; including 116,823*l.* unemployment relief works 357,154*l.* Cheshire, 301,204*l.* Cornwall, 204,928*l.* Derbyshire, 251,562*l.* Durham, 247,931*l.* Gloucestershire, 228,598*l.* Lincolnshire (Lindsey), 236,121*l.* Middlesex, 327,148*l.* Norfolk, 289,925. Northamptonshire, 274,089*l.* Northumberland, 239,700*l.* Shropshire, 222,871*l.* Somerset, 334,638*l.* Southampton, 284,228*l.* Staffordshire, 272,352*l.* Surrey, 391,959. Sussex, East, 244,521*l.* Warwickshire, 224,080*l.* Wiltshire, 227,037*l.* North Riding of Yorkshire, 266,574*l.* Glamorgan, 218,472*l.*

Totals for Counties.—11,852,773*l.*, including, in respect of unemployment relief works, 743,252*l.*

Grants to County Boroughs.

(*(a)* total; *(b)* in respect of unemployment relief works.)

Exceeding 100,000*l.*—Birmingham *(a)* 130,544*l.*; *(b)* 15,297*l.* Newcastle-upon-Tyne *(a)* 174,539*l.*; *(b)* 142,354*l.* Sunderland *(a)* 155,983*l.*; *(b)* 149,713*l.*

Exceeding 50,000*l.*—Bournemouth *(a)* 60,139*l.*; *(b)* 30,032*l.* Bristol *(a)* 89,781*l.*; *(b)* *nil.* Kingston-on-Hull *(a)* 67,395*l.*; *(b)* 56,447*l.* Leeds *(a)* 79,399*l.*; *(b)* *nil* (maintenance, 24,065*l.*), other purposes, 55,334*l.* Liverpool *(a)* 50,705*l.*; *(b)* *nil.* Rotherham *(a)* 58,832*l.*; *(b)* 49,965*l.* Sheffield *(a)* 52,157*l.*; *(b)* 17,242*l.*

Total for county boroughs *(a)* 1,998,149*l.*; *(b)* 502,504*l.*

GRANTS TO LONDON AUTHORITIES.

In respect of maintenance.—On roads and bridges in Classes I and II; to the London County Council, 47,771*l.*; to Metropolitan Borough Councils, 407,398*l.*; on scheduled roads, *nil*; in respect of other purposes, 35,906*l.* Total, 443,304*l.*

OTHER UNEMPLOYMENT RELIEF GRANTS.

North Orbital Road, London, 50,310*l.*; Unemployment Grants Committee (Loan Charges), 962,718*l.* River Mersey Road Tunnel, 1,226,821*l.*

GRANTS TO LONDON AUTHORITIES.

London County Council, 49,513*l.*; Metropolitan Boroughs, 393,791*l.*; Total, Administrative County of London, 443,304*l.*; including, in respect of maintenance, Class I and Class II roads and bridges, 407,398*l.* Scheduled roads, *nil*; unemployment relief works, *nil*; other purposes, 35,906*l.*

MILEAGES OF ROADS: MARCH 31, 1928.

Class I.—England and Wales, 19,420; Scotland, 5,719; Great Britain, 25,139.

Class II.—England and Wales, 12,041; Scotland, 3,645; Great Britain, 15,686.

Both Classes.—England and Wales, 31,462; Scotland, 9,364; Great Britain, 40,825.

Scheduled, or third class roads: England and Wales, 42,249; Scotland, 12,804; Great Britain, 55,053.

Classified and Scheduled Roads.—England and Wales, 73,710; Scotland, 22,169; Great Britain, 95,879, or 53·6 per cent. of all roads.

England and Wales.—All main roads, 31,200; all district roads, 108,988; county borough roads, 11,439; London roads, 2,212. Total, England and Wales, 153,838.

Scotland.—Counties, including burgh roads in charge of counties, 22,586; other burghs, 2,490. Total, Scotland, 25,076.

Grand Total, Great Britain: 178,914 miles. An increase of about 130 miles.

Increase in mileage of main roads in England and Wales, 1925–1926, 1,100; decrease in mileage of district roads, 950.

REGULATIONS FOR WHEELS AND LOADS.

(See Addenda for new regulations.)

Traction Engines.

The regulations as to tyres of traction engines cited in the preceding issues of the Year-Book may be regarded as obsolete. The concerted action now being taken to encourage the use of tyres which will not damage the roads is leading to good results. New regulations will probably be withheld until some defined policy as regards the classification of these vehicles can be adopted, especially as relating to agriculture on the one hand and long-distance transport on the other. The tendency of practice as regards transport of goods is towards the use of small tractors with rubber tyres for work, such as local furniture removals, and the use of heavy vehicles of one of the two 6-wheeler types for higher-powered transport over long distances, except where ordinary steam wagons and lorries suffice. The scope of the old-fashioned heavy traction engine is becoming much reduced.

Heavy Motor-Cars.

This term applies to motor vehicles weighing more than 2 tons unladen, and refers to three distinct classes: (1) Motor wagons or lorries; (2) traction engines not exceeding 5 tons in weight and in other respects fulfilling the requirements; and (3) delivery vans and omnibuses, provided with rubber tyres and allowed to travel at 12 miles an hour.

Maximum Weight Heavy Motor-Cars.—The vehicle unladen, 7½ tons; vehicle and trailer, unladen, 9¾ tons; 'axle-weight' (any pair of wheels with their full load), 8 tons; axle-weight of trailer, 4 tons. An amending order of 1922 which, to meet special cases, allows 22 tons for the total of axle-weights and 6½ ton trailer axle-weight, will probably soon be superseded, but the necessary increases for tyre widths, in the table, can easily be calculated for such a case. This Order allows for a speed of 12 miles per hour if all the wheels have soft tyres, and the total length does not exceed 33 feet.

Tyre Widths.—These are: minimum for the vehicle itself, 5 ins.; minimum for the trailer, 3 ins. All wheels: ½ in. for each 'unit of axle-weight,' which is, 7½ cwt. for a 3-ft. diameter wheel, 1 cwt. more for every 12 ins. more, and 1 cwt. less for every 6 ins. less diameter. These rules do not apply to wheels with rubber tyres.

Heavy Motor-Car (Amendment) Order, 1927.

The chief provisions of the Heavy Motor-Car (Amendment) Order, 1927, may be summarised as follows :

Overall length of the vehicle not to exceed 27 ft. 6 ins. A vehicle more than 26 ft. in overall length may not draw a trailer. (See below.)

In the case of public service vehicles, one brake shall be applied by a pedal, and the operation of either brake shall not in any case disengage the engine from the transmission gear.

Public Service Vehicles : an axle-weight must not exceed 5½ tons, and the sum of such weights 9 tons. For other heavy motor-cars the figures remain 8 tons and 12 tons respectively. (See below.)

Six-wheeled Rigid Frame Vehicles : maximum overall length, 30 ft. ; greatest unladen weight, 10 tons.

Axle-weights : the sum of the registered axle-weights shall not exceed 12 tons for a public service vehicle, nor 19 tons for other vehicles ; individual axle-weights shall not exceed 4½ tons for public service vehicles, nor 7½ tons for other vehicles.

Heavy Motor-Car (Amendment) Order, August 9, 1928.

The effect of this order is : speed limits (now superseded by the Road Traffic Act, 1930 ; see Addenda) ;

Heavy Motor-Car without Trailer.—(*a*) With pneumatic tyres, 20 miles per hour ; (*b*) with solid rubber tyres or partly with solid rubber tyres, and partly with pneumatic tyres, 12 miles per hour ; (*c*) wholly or partly with metal tyres, unladen weight not exceeding 3 tons, and registered axle-weight of any axle not exceeding 6 tons, 8 miles per hour ; (*d*) any other case, 5 miles per hour.

Heavy Motor-Car with Trailer.—(*a*) Articulated vehicle fitted throughout with pneumatic tyres or solid rubber tyres, 12 miles per hour ; (*b*) vehicle with ordinary trailer : Vehicles and trailer fitted entirely with pneumatic tyres, 12 miles per hour ; vehicle and trailer fitted with solid tyres, or partly with solid rubber and partly with pneumatic tyres, 8 miles per hour ; any other case, 5 miles per hour.

Tyre Width, Camber, and Pressures.—The value of width of tyre in reducing the pressure of the wheel upon the road crust is not fully operative even on flat roads, since the wider the tyre the more frequent are the occasions on which it fails to bear for its full width on the slightly uneven surface of the road. The effect of width in reducing pressure has a more definite limit on hard roads with a sharp camber, unless the road is wide, with sloped and not barrelled camber, and the vehicle travels wholly to one side of the middle line. On a barrelled camber, the vehicle does not rest upon the full width of its tyres even when keeping to one side of the road. Traction engines traversing narrow roads tend to wear them into a pair of parallel flat strips, with an exaggerated cambered part in the middle. Since the reduction of bearing width is a serious matter, and, apart from unusually troublesome vehicles and difficult roads, applies to many classes of vehicles on properly made roads, and even to tyres no wider than 3 ins. or 4 ins., it is necessary to take it into account in the development of vehicles and roads. In the first place, it is desirable to find what is the average relation between diameter and tyre width as regards pressure, a relation which depends upon the modulus of elasticity of the crust and other factors. Since, however, wheels of large diameter punish the road less than wheels of small diameter, even when the actual pressures (load per sq. in. of surfaces in contact) are somewhat higher, the position generally may be no worse even if we fail for some time to establish the true relation and make the tyres of large diameter wheels somewhat too narrow. A general increase in the diameters of the wheels of many vehicles is, then, to be aimed at. The principle is recognised in the regulations for heavy motor cars. Next, as regards tyres which are necessarily very wide, attempts should be made to design the vehicles so that some duly constrained side play, angular or bodily, is permitted to the wheels. The side play which the wheelwright, with centuries of experience behind him, gives to cart and wagon wheels, greatly tends to economy in the wear and tear of the vehicles and the road, side play taking place to a large extent between the greased axle and the hubs of the wheels instead of occurring as a rubbing of the wheels on the road. The play is partly axial, but to a small extent angular, and allows of a slight adjustment to the cambered road. Thirdly, dead flats on roads (no gradient) should, as opportunity arises, be converted to gradients of 1 in 200, or steeper, and the camber reduced. On steeper gradients, and with some road crusts and subsoils, a nearly flat camber is suitable, and in other cases a slight tilt to one side only may be given to the whole crust.

Tyre Widths for Horse-drawn Vehicles.—Under the Highways and Locomotives Amendment Act, 1878, a county authority may make regulations for tyre widths of vehicles drawn by animal power, in proportion to the loads carried. The following examples of such regulations are taken from 'The Surveyor and Municipal and County Engineer,' April 21, 1911.

Tyre Widths for Certain Loads: Horse-drawn Vehicles.

Four-Wheeled Vehicles.—Tyre width, 2½ ins., about 3 tons in several counties. Width, 3 ins., 2 tons 11 cwts. ; 2 tons 19 cwts. ; 3 tons 1 cwt. ; 3 tons 11 cwts. ; width, 3½ ins., 3 tons 1 cwt. ; 3 tons 11 cwts. ; 3 tons 19 cwts. Width, 4 ins., 3 tons 1 cwt. ; 3 tons 11 cwts. ; 3 tons 19 cwts. ; 4 tons 1 cwt. Width, 4½ ins., 3 tons 11 cwts. ; 3 tons 19 cwts. ; 4 tons (summer ⊗). Width, 6 ins., 4 tons 1 cwt. (winter ⊗) ; 5 tons 1 cwt. ; 6 tons 1 cwt. Width, 9 ins., 5 tons 1 cwt. ; 6 tons 1 cwt.

Two-Wheeled Vehicles.—Tyre width, 2½ ins., 1 ton 1 cwt. Width, 3 ins., 1 ton 1 cwt.; 1 ton 11 cwts.; 1 ton 11 cwts. (winter); 1 ton 17 cwts. Width, 4 ins., 1 ton 11 cwts.; 2 tons 1 cwt.; 2 tons 11 cwts. Width, 4½ ins., 1 ton 11 cwts.; 1 ton 17 cwts. (summer); 2 tons 1 cwt.; 2 tons 11 cwts. (summer). Width, 6 ins., 2 tons 11 cwts.; 2 tons 17 cwts. (summer); 3 tons 1 cwt. Width, 8 ins. and 9 ins., 3 tons 1 cwt.; 9 ins., 2 tons 17 cwts. (winter).

Table I.—Legal Speed Limits of Motor Vehicles, 1931.

Abbreviations.—a.w. = all wheels. Fitted with: p.t. = pneumatic tyres, s.e.t. = soft or elastic tyres. N.T. = when not drawing a trailer. D.T. = when drawing a trailer.

Class of vehicle.	Miles per hr.
Passenger Vehicles.—(1) if a.w.p.t. and N.T.:	
(*a*) if not adapted to carry more than 7 passengers exclusive of the driver and is not a heavy motor car nor an invalid carriage	no limit
(*b*) if a heavy motor car or adapted to carry more than 7 passengers exclusive of the driver	30
(2) In any other case, including invalid carriages	20
Goods Vehicles.—(1) N.T. (*a*) motor cars; a.w.p.t., and (*b*) heavy motor cars constructed or adapted for the conveyance of horses and their attendants and used solely for that purpose; if a.w.p.t.	30
(*c*) (i) Motor cars, a.w. not p.t. but are s.e.t.; and (ii) heavy motor cars a.w.p.t.	20
(*d*) heavy motor cars a.w. are not p.t. but are s.e.t.	16
(2) D.T. (*a*) if a.w. of the vehicle and trailer are p.t., or if the trailer is attached to the drawing vehicle by partial superimposition in such a manner as to cause a substantial part of the weight to be borne by the vehicle and a.w. of the vehicle and trailer are s.e.t.	16
(*b*) if a.w. of vehicle and trailer are not p.t. but are s.e.t.	8
(3) In any other case	5
Locomotive and Motor Tractors.—(1) *Heavy Locomotives.* (*a*) within any city, town, or village	3
(*b*) elsewhere	5
(2) *Light Locomotives.*—When N.T. or not more than two trailers, if a.w. of the locomotive and of any trailer drawn by it are s.e.t.	8
(*b*) In any other case	5
(3) *Motor Tractors.*—(*a*) N.T., if a.w., s.e.t.	16
(*b*) D.T. of a.w. of the tractor and any trailer are s.e.t.	8
(*c*) In any other case	5

French Road-Surface Tests.

The following figures are given as those experimentally determined by the Paris police for the distances in which a motor-car weighing a ton and three-quarters, travelling on the level at 19 miles an hour, can stop on various kinds and conditions of road surface:—

Dry granite, 26 ft. 3 ins.; very wet granite, 32 ft. 10 ins.; greasy granite, 65 ft. 7 ins.
Dry wood, 26 ft. 3 ins.; very wet wood, 46 ft.; greasy wood, 65 ft. 7 ins.
Dry asphalt, 32 ft. 10 ins.; very wet asphalt, 59 ft.; greasy asphalt, 82 ft.

Table II.—Steam Rollers.

(Ordinary Loads and Dimensions in Working Order.)

Description of Roller.	Driving Wheels.				Front Rollers (as a whole).				Wheel Base.		Width Rolled.	
	Diam. in Ft.	Tread of each, Ins.	Load on both, Tons.	Load per In., Cwts.	Diam.	Tread in Ins.	Load in Tons.	Load per In., Cwts.				
					Ft. In.				Ft. In.		Ft. In.	
'Ten-ton'	5¼	16	7·25	4·5	4 0	49	3·75	1·6	11	2	6	4
'Twelve-ton'	5¼	16	7·9	4·9	3 10	49	4·3	1·7	11	3	6	4
'Fifteen-ton' or 'Sixteen-ton'	6	20	9·75	4·9	4 6	54	6·5	2·4	12	8	7	4
		18		5·5								

Diesel Engined Rollers.

Tandems: weights, empty and ballasted, 6 and 8 tons, 8½ and 10 tons.

Three-Rolls: weights, empty and ballasted, 11½ and 13¾ tons; front roll, 4 ft. diam. by 4 ft. 2 ins. wide; rear rolls, 5 ft. 6 ins. diam. by 17 ins. wide; rolled width, 6 ft. 9 ins.

Six-wheeled Steam Wagon (Garrett): capacity, 12 tons; body, 22 ft. by 6 ft. 9½ ins. First wheel base 13 ft. 4 ins.; second wheel base, 3 ft. 10½ ins., the four driving wheels being driven by one differential gear.

Six-wheeled Omnibus (Daimler): rigid type; covered top; wheel base to midway between rear axles, 17 ft.; rear axles, 3 ft. 6 ins. apart; total wheel base, 18 ft. 9 ins.; rear overhang, 8 ft. 3½ ins.; maximum outside width of body, 7 ft. 6 ins.; turning circle, 60 ft.; rear axle clearance, 6½ ins.; passengers, 104, 45 on lower and 59 on upper deck. (Used for transport of works staff.)

Passenger Chassis (Dennis): frame height, 24½ ins. ('one-step' type); wheel base, 16 ft.; rear axle clearance, 7 ins.; passengers, with omnibus body, 33, or less; with coach body, 30, or less.

Low-Loading Vehicle.—Two-tonner; hand gear end-tipping; height from roadway, 5 ft. to top of side, about 4 ft. to top of half side (flap down); tips to 45 deg.; 140 cu. ft. capacity, or 5·2 cu. yds.

Caterpillar Tractors, 10-ton and 5-ton: in use with street scrapers; as at Blackpool and at Lichfield, the latter drawing a train of three self-loading scrapers.

Pneumatic Tyred.—Public service vehicles; cesspool emptier (Dennis); 1000 gal.; 6-ton chassis. Cleansing wagon (Halley), 7 cu. yd. capacity. Also many other vehicles.

RESISTANCE TO TRACTION.

TABLE III.—INFLUENCE OF DIAMETER OF WHEELS.

The following figures are taken from the results of experiments by General Morin:—

Pull in lbs. per 2,000 lbs., at 3 miles an Hour.

Nature of Road.	Cart without Springs. 4½-inch Tyres. Diameter of Wheels in Inches.		Wagon without Springs. 4½-inch Tyres. Diameter of Wheels in Inches.	
	64	80	36 and 60	44 and 78
	Lbs.	Lbs.	Lbs.	Lbs.
Earth road, very good, nearly dry	55	44	74	63
Gravel road, loose gravel on firm earth	143	114	190	163
	168	134	225	192
	180	144	241	206
Broken stone road:—				
In good condition, dry	30	24	40	34
Firm, little soft mud	55	44	74	63
Portion worn out, thick mud	80	64	107	92
Stone block pavement, fair condition, dry	25	20	34	29
Thick oak bridge floor	35	28	47	40

Influence of Width of Tyres.

Under some circumstances narrow tyres offer less resistance to traction than wide tyres, but these circumstances are unusual, or in themselves undesirable, or do not hold in all kinds of weather. For instance, narrow tyres will cut through stiff mud on a hard bottom better than tyres which, though wider, are not wide enough to ride over the mud by pressing it in a rut of moderate depth. Wheels will run along ruts made by wheels with wider tyres, but not in ruts made by narrower wheels. Narrow tyres will run through a layer of loose stones on a hard road better than wide tyres, and they allow of the vehicle being pulled out of a slough which would hold down wider felloes. Generally, however, tyres classed as wide offer less resistance than tyres classed as narrow, and the more so when their cumulative effects on soft roads are considered, as well as the comparison of the moment. It is important to note that a vehicle which, on soft roads, can be pulled more easily than a similar vehicle with narrower tyres, will still show some advantage on a hard and firm road, or will not be at a disadvantage; and it must not be overlooked that in hot weather the tractive effort with narrow tyres is very high on asphalt pavements and even considerably increased on tarred roads.

The following are extracted from a table in which 1½-in. tyres and 6-in. tyres are compared, the figures given being 'resistance to traction in lbs. per ton' (*Ira O. Baker*).

TABLE IV.—INFLUENCE OF WIDTH OF TYRES.

Description of Road.	Width of Tyres. 1½-inch.	6-inch.
	Lbs.	Lbs.
Broken stone road, hard, smooth, no dust, no loose stones, nearly level	121	98
Gravel road, hard and smooth, few loose stones, size of black walnuts	182	134
Gravel road, new gravel, not compact, dry	330	260
Gravel road, wet, loose sand, 1 in. to 2½ ins. deep	246	254
Earth road, loam, dry, hard, no dust, no ruts, nearly level	149	109
Earth road, loam, stiff mud drying on top, spongy below	497	307
Earth road, clay, dry on top, but spongy below	618	464
Earth road, clay, stiff, deep mud	825	551
Earth road, loam, mud, 2½ ins. deep, very sticky, firm below	251	325
Earth road, clay, sloppy mud, 3 to 4 ins. deep, hard below	286	406
Earth road, loam, dry, loose dust, 2 ins. to 3 ins. deep	90	106

Tractive Effort on Different Pavements.

These experiments (*Ira O. Baker*) provide important comparisons between pavements differing only in condition as well as between pavements of different kinds. For instances the pulls in lbs. per 2,000 lbs. were: on considerably worn wood blocks, 36; on asphalt at 42° F., 34; on oak plank, nearly new, 32; and on smoothly-dressed granite blocks, 30; but the 32 for oak plank rose to 38 when it had been worn down ¼ in. in many places; and the 34 for asphalt rose by 3 lbs. with a rise of 10° in temperature, and was 70 lbs. when the temperature was 84° F. On cedar blocks, a pull of 50 lbs. when they were covered with ¼ in. of crushed gravel, rose to 90 lbs. with a ½ in. covering of silica pea gravel. On a brick pavement, ¼ in. of dust raised the pull from 17 lbs. to 31 lbs. On a steel plateway a pull of 19 lbs. was raised to 28 lbs. by ⅛ in of fine dust, and to 40 lbs. by ¼ in. of powdered stone. Out of a number of brick pavements the best required a pull of 17 lbs. per 2,000 lbs., and a granite macadam crust only 18 lbs.

Ministry of Transport, 1928; concrete surfaced roads; solid rubber tyres; 40-in. diameter wheels, 100; 21-in. diameter wheels, 90; relative tractive efforts.

At 15 miles per hour: 40-in. diameter solid rubber tyres, 33 lbs. per ton.

Rubber and Iron Tyres.

Experiments made in 1895 showed that the tractive effort is less with pneumatic tyres than with solid rubber or iron, and that the advantage increases with increase of speed. Iron tyres were better than solid rubber on good or ordinary pavements, but required a somewhat greater pull on bad, irregular pavements.

Effect of Speed.—Experiments by Morin showed an increase of tractive effort with increase of speed. The differences between the pulls required at a walk and those at a fast trot were considerable, as were those between the pulls at a 'trot' and 'a fast trot.' Other experiments showed a very small increase with pneumatic tyres and much greater increases with solid rubber and with iron tyres.

Undulations.—The effects of the passage of large numbers of heavy or fairly heavy vehicles of identical form, and the less serious effects of the same nature caused by the passage of many vehicles of similar weights and similarly sprung, have led to the forming of undulations of the same generic class as strings of puddles. Diversity in design and springing is favoured by road engineers, and 'fleets' of exactly similar vehicles are regarded as specially injurious. Direct action is hardly practicable, but the tendency to favour diversity seems likely to gradually effect some practical results.

ROAD CONSTRUCTION.

(By Reginald Ryves, M.Cons.E., Assoc.M.Inst.C.E.)

Country Roads.

Widths of Roads.—The total width given to a new road should include provision for: (1) the carriageway; (2) the supports for the edges of the crust, such as rough stone or gravel shoulders or 'water tables'; (3) such further strips of grass or other margin as may be necessary to hold drifted snow, to provide for the admission of air currents, or to keep sub-soil water at a suitable distance from the crust; (4) footways; (5) side ditches where necessary; (6) catch-water drains where necessary; (7) fences, and, where other parts of the width are not available, places for planting shade and shelter trees.

The engineering cost of making a road, especially where there are considerable earthworks, may be reduced by locating the footway outside the main formation width. The ground surface may lend itself to this; or the footway may be on a berm of the side of a cutting; not on the slope of an embankment, unless a high and dense hedge is between the footway and the carriageway. Overhedge location is very economical, especially if the path need not be fenced off from the field.

Width of Carriageway.

Width of Carriageway.—Maintenance is the dominating factor where traffic is light. Under the item 'carriageway' in the provision for total width allowance may be made for probable future widening, having regard to the relative economy of widening alternative routes or making new roads. In hilly country, and especially on sidelong slopes it is usually better to allow no such provision between fences, since the future can best be cared for by acquiring land only, the cost of obtaining a given width of flat strip by two earthworks being usually very much less than that of obtaining the same width by one earthwork. For the one wide strip the quantity of earthwork is much greater and the rate for cutting may be higher, while the retaining wall will cost much more than the two smaller ones. With flat earth slopes the total width required may be as great or greater.

Width in Relation to Maintenance.

Width in Relation to Maintenance.—The best width, having regard to the nature and amount of the traffic, will depend upon the materials available and their cost. One width will give a minimum maintenance cost with a hard and costly stone, a greater width may be the most economical for a softer stone. First decide the economical width for each material, and then compare costs. When the traffic is moderate the 'weathering' factor may be important and on little-used roads it may predominate. Usually the economic width for sandstone and flint crusts is greater than that for limestone crusts, partly because the more porous crusts made with sandstone and flint may have flatter cambers, tending to a good distribution of the traffic, and partly because the quartzy materials wear into large grains which are only removed by the heavier rains, while limestone crusts wear into fine stuff which is readily removed. The exposure of a wide surface is, therefore, usually undesirable with limestone crusts. Similar comparisons are furnished by harder stones, such as quartzites, compared with granites which contain much felspar. The nature of the subsoil affects the width, especially if the cost of construction or reconstruction has to be considered, because with soft subsoils, not tolerant of high pressures under heavy wheel roads, it may be better to reduce the pressure by making a deep crust than to reduce rutting or surface wear by making a wide crust.

Width and Traffic.

Width and Traffic.—The width may be decided, partly or wholly, from the traffic point of view. In making a mountain road, or widening a narrow lane, the ruling width may be that necessary for the passage of two loaded vehicles, and, as a matter of safety, a road with walls may be made somewhat wider than a similar road with hedges. In such cases it is important that the edges of the crust should not be steeply cambered or weak, since such conditions reduce the effective passing clearance. On roads of this kind the carriageway is that imposed by the total width, but it is often good economy to carry the actual crust right across, with such change in the nature of the materials near the edges, as may be suggested by the relative importance of the margin as a support to the crust or as a surface drain. Apart from such cases, and taking that of the normal carriageway on a road with suitable margins, the widths suitable are, for a very large mileage of country roads generally, either that required for one vehicle at a time, but sufficient for the cautious passing of two vehicles, or that required for the frequent and convenient passing of two vehicles. In both cases, it is desirable to give ample support to the edges, either by under-trenching, with a filling of large-gauge stone, or by continuing the crust under the turf beyond the incidence of wheel loads. Using the word as applying to the measurement from surface margin to surface margin, the following widths are regarded as suitable. For single-line traffic, 12 ft. is a width largely adopted in many countries. Ten feet or even 8 ft. may be sufficient for roads with very little traffic if the soil is suitable and the margins readily accessible. A gravel soil, especially if these strips be sifted a little when the road is made, offers this advantage, as does, under some conditions, a sandy soil. On clay soils, the width of the crust itself should be such as to admit of the passing of vehicles, or the edges of the crust may be broken down by rutting of the clay just beyond. Clay is not easily brought back to its proper level. On account of its hardness in dry weather, however, it makes good margins for narrow 'fair weather' roads, which may be made with a very narrow metalled or gravelled width. For roads on which the passing of two vehicles must be readily accomplished, a width of 16 ft. is very usual, and 15 ft. is enough in countries in which the ordinary vehicles are narrow. In France a considerable mileage of important roads has a carriageway of about 16½ ft., but this may, in some cases be the economical maintenance width. The usual width of the carriageways of the French Routes

Nationales is from 5 to 7 metres, or say, 15¾ to 23 ft. An important system of English county roads has an average width of 17½ ft. On very steep gradients it is often desirable to have very wide carriageways.

Except where local conditions demand a greater width, 30 ft. is a sufficient width for the carriageway of any but important arterial roads, other roads locally carrying very much traffic and parts of roads where vehicles are often standing. The best widths for traffic are not multiples of some unit even when such a unit can be decided upon. The best allowances for clearance depend upon the nature of the road. The necessary dimensions for clearances between vehicles depend on the nature of the margins and, in the case of a mountain road, may reasonably be small, having regard to the cost of construction and the moderate speeds which are proper to traffic on such roads. In the case of a road carrying much traffic, there is danger in having a carriageway less than some dimension depending upon how many lanes of traffic are provided for; but there may also be danger in providing a carriageway of a width considerably greater than that which is suitable. Thus, of two roads which are similar in other respects, the more costly may be the less efficient. The matter of width is one for judgment rather than for rules or formulas.

Camber.

Camber.—The amount of camber may be stated as the total rise in the width of carriageway or as the average slope of the sides. A rise of one-fiftieth is often recommended, or slopes of 1 in 25. Slopes of 1 in 32 have been recommended as an average. Actually, the amount of camber depends upon the nature of the crust, the gradient, the nature of the traffic, the widths and the climate, and no general rules can be laid down. It may be noted, however, that a rise of more than 1 in 50 should not be given without careful consideration to roads with much motor traffic, while there are some roads, especially those with quartzy crusts on steepish gradients, which require hardly any camber. The barrelled camber has the advantage that the support which the earth margins give to the edge of the crust is less nearly horizontal than in the case of a sloped camber (two slopes joined by a small arc in the middle of the road), and the barrel form resists somewhat better a tendency to the formation of ruts on each side of the middle line. The former advantage disappears, however, if the edges of the road crust are suitably designed, and the barrelled camber has the serious disadvantage that the slope becomes steeper near the edges where cyclists ride when they are being passed by motor cars. On roads with much motor traffic the mud is soon shifted to near the edges, this part being often somewhat slippery. An elliptic camber has sometimes the disadvantage that it is too flat in the middle, especially on roads with much motor traffic and of such width that a strip of about 5 ft. width in the middle gets the main part of the wear of the off-side wheels of cars going both ways. The camber with two slopes seems suitable for a greater range of roads than the barrelled form, and the advantage of a tilt to one side only must not be overlooked in the special cases to which such a device applies.

Super-elevation.

There is no theoretically correct degree of super-elevation at a bend on a road. Super-elevation for maximum speeds would render the road unsafe in respect of encounters of vehicles at bends, besides causing inconvenience and danger in the case of a vehicle travelling slowly. Even if attempts were made to impose degrees of super-elevation calculated for some moderate speed the results would, at some places, be unpractical. Successful application has been made of the principle of adopting a moderate speed, or a small range of speeds for primary calculations, with a limit of super-elevation expressed either as an angle or in inches. It may be desirable to use both limits, in order the better to deal with the great range in the degrees of curvature.

There remain cases in which super-elevation cannot be applied, as at snake bends, or can only be applied in an unsatisfactory manner, as to half a snake bend, or, in the case of a very short bend, inconveniently as regards the merging of the cross slope into the normally cambered straight road.

On some roads, properly applied super-elevation is a great improvement, especially the slight super-elevations suitable for tortuous mountain roads.

Drainage.

Specific works may come under one or more of the four heads: (1) interception of surface waters which would flow across the road, or along it, or would flood it; (2) interception of seepage water; (3) surface drainage of rain-water from the road and its margins; (4) under drainage of the road bed and crust. In a soil neither very stiff nor very porous, a side ditch may perform all four duties. When on the uphill side of a road it acts as a catch-water drain. It also acts as a channel to carry to suitable outlets the rain-water gathered by the road. It may also intercept seepage water from the hillside or the land above a sunken road; and, if near enough to the edges of the crust, and deep enough, it provides for the establishment of an hydraulic gradient from the crust and the road bed to the ditch bottom or water-level. On a stiff soil it does not perform this function, except to a very limited extent and when deep and close to the crust.

In a stiff soil, therefore, a deep ditch is not needed for this purpose, the water being dealt with by surface flow, aided by the filling of all hollows, and by evaporation. A deep ditch may, however, play the part of an interceptor of seepage water, forced through a fairly stiff soil from wet places on the hillside above. Apart from such a purpose a ditch on a stiff soil may be shallow if the necessary capacity can be given by the width available. The stiffer the soil the deeper the drain, up to a point at which it will no longer drain the road bed and may be quite shallow. It is then very important to fill hollows on all parts of the roadside which are above the level of the underside of the crust.

Catchwater Drains.—It is often desirable to have a catchwater drain clear of the uphill fence so that the bank may not be torn by water running down it. The outlets may be clear of the road, or lead to the larger cross culverts. Such a drain and, when necessary, side drains, may be provided with 'drops' or falls of hard materials, to reduce velocity and scour. Catchwater drains are much needed on many English roads.

Side Drains.—For a given soil there is a slope at which water hardly moves through it. To provide for flow, a slightly *steeper* slope, carried from the bottom of the side ditch or shoulder drain, should reach the edge of a waterproof crust, or the middle of a porous crust. This determines the depth of the ditch, or the depth at which the pipe drain in the shoulder trench lies; or it decides which of them will be the cheaper to make and maintain. On porous soils the natural slope of the land may provide drainage; but even then care must be taken that when the road runs directly down the slope there is some easier way for the water to flow than down the road bed and out through the crust; and sudden changes in the soil must be noted and provided for. On a long slope of this kind, on a porous soil, some diversion of subsoil water by trenches filled with clay may be useful, where the water can be turned to a depression in the ground outside the road. Pipe cross drains may be used for the same purpose, and if backed by clay on the downhill side will be very effective.

Drainage of the Crust.—This comes under one or two of the main divisions of drainage; surface drainage being the more important on stiff soils, and under-drainage on porous soils, while it may be necessary to make the most of both on soils such as those marls and silts which are at once receptive and retentive of water. If the crust is more porous than the road-bed and subsoil it will probably be desirable to provide a drainage course, or bottoming, such as a telford pavement. If the soil is more pervious than the crust such a provision is not likely to be necessary for drainage. When the crust or its bottom course allows of drainage to the sides, but not very rapid drainage, this may be aided by giving a camber to the road-bed, which may also be desirable so as to provide sufficient thickness of crust where it is most wanted, towards the edges. Cross-drains are seldom economical. If they are farther apart than the width of the road they are less effective than shoulder drains: if they are nearer together than the width of the road, they cost more than one shoulder drain, or, as they have to be placed deeper, as much as both shoulder drains. Cross drains require many more outlets than shoulder drains. Camber is given to a road so that water may drain from the surface of the crust. Too steep a camber may defeat its object by driving traffic to the middle, so that ruts are formed. When a road is puddled by much traffic in drizzly weather, camber is ineffective as the little ridges of mud hold up the water. On a slope of 1 in 24 a ½-in. ridge of mud holds up a foot-wide puddle; on places worn flat very much wider puddles. Under such conditions the best drain, on an impervious road, is a broom. When the crust is porous and self-draining a very small camber is sufficient, but the outlets to the side ditches must be sufficiently numerous and effective, or the road will be flooded during rain. On a road with no gradient it may be necessary to have flush edges, that is, no raised water-tables; but with a very small gradient this is unnecessary as the water will flow to the outlets. To prevent scour and the cutting back of their beds till the crust and road-bed are attacked, the outlets through turf margins must not carry the water with too high a velocity. The formation of a delta with the road washings may be allowed, the stuff being cleared away when the level of the delta becomes too high and the outlet is ineffective. Generally, a porous road crust need not have a steep camber if any of the following conditions are fulfilled: (1) good drainage of the crust, with shoulder drains if necessary; (2) a porous subsoil with a low, normal subsoil water level; (3) a porous subsoil on an embankment, or drained by effective side ditches. An *impervious* crust need not have a steep camber—(1) on gradients, especially if fairly steep; (2) if kept clean; (3) in dry and in showery climates or where the rains are usually heavy, as opposed to damp and drizzly climates.

Drought.

Owing to the presence of clayey matter as a constituent of many important road stones the weakness of road crusts when too wet has received more attention than their weakness when too dry. Sandy materials, on the other hand, resist wheel loads and disturbance generally better when damp than when dry. Drought, therefore, injures such roads, including crusts made with quartzite, sandstones, and flints (apart from dust as a nuisance). Other roads may be seriously affected by droughts, which cause a crumbling of the margins, or the gaping of a clay soil, the effects being observed when heavy rains occur. Drought may be combated by shade, either of trees or hedges, and by care in carrying out drainage so that the soil is not made too dry. Dead leaves are beneficial on sandstone and flint roads, and various materials, more or less imitative of the gummy decay of the leaf, have been used to lay dust, or to bind road crusts of a sandy character.

Roadside Trees.

For a fuller presentment of the subject see *The Surveyor*, August 9, 1907; and a summary of main points with notes relating to road surfacings of the new types, in the same journal, June 5, 1925.

The chief and prevailing influence exerted by trees on the road crust is a great reduction in daily or annual ranges of crust temperature, which facilitates design in some particulars. The effect in reducing maximum temperatures, separately considered, is next in importance in some cases. In other cases, notably with broken-stone, water-bound, and gravel or flint crusts, the effect of the trees in screening the road from loss of heat by radiation is the more important.

Shade in Summer.—The value of shade, apart from comfort, is in a reduction of evaporation from macadam and flint roads, reducing the tendency to disintegration in dry spells. On tarred roads it prevents licking up of the tar and the formation of ruts, and prolongs the life of the film. In the case of concrete roads the reduction of maximum crust temperatures reduces the tendency to the forming of cracks. On asphaltic and bituminous roads it either reduces the rutting and wearing effects of traffic, or, when its effect is taken into consideration in designing the crust or carpet, it is possible economically to construct a more efficient carpet, less hard and less slippery than one intended to withstand the effects of a whole day of hot sunshine.

Screening Effects.—While some trees, such as the elm, have a greater frost-screening effect than others, such as the ash, all have an important effect in decreasing the range of temperature to which the road crust is subjected, in one day or in one year. Generally, they reduce very much indeed the number of occasions on which a road is slippery because frozen. By lessening the severity of freezing and by afterwards screening the frozen surface from the full effects of sunshine, trees save macadam and flint roads from most of the licking-up after frosts. They also, by mitigating the effects of severe frosts, save such roads from disintegration due to the formation of ice within the crust. Slipperiness due to hoar frost, or to the freezing of condensed mist or drizzle on a cold road, is much worse on the new surfaces than it is on water-bound macadam, so that, in this respect, the value of the tree is increased by the new conditions in winter and early spring.

General Policy.—The significance of trees in the above respects is now widely recognised. Further, there is a reaction against the planting of trees in too formal a manner, as, for instance, in avenues which do not suit the locality or express any characteristic of the stretch of road. Clump treatment is being advocated by a number of surveyors, and it is realised that the principle may be applied broadly in respect of the planting or treatment of roadside trees and hedges.

For a recent study of the road and roadside in relation to the landscape, see *The Surveyor*, March 8, 1829 (A. D. C. le Sueur), and editorial comment March 15.

The Strength Crust and the Wearing Layer.

The word ' foundation ' is often misapplied. It should properly be used for the special bottoming that is necessary on soft soils, and sometimes on clayey soils, in order that a distinction may be made between such preparatory work and the construction of the actual ' crust,' which plays the principal part, or is the sole agent, in distributing the load. The essential nature of the crust is the same, whether it distributes the wheel loads upon the natural soil or upon a bottoming of hard material, and whether it receives the wheel loads in their full intensity or partly distributed by a carpet of considerable strength and thickness. Thus, the so-called ' concrete foundation ' of a wood-paved road is really the strength crust, and the wood-paving is the carpet or wearing layer, and on a bad natural soil the concrete crust will need something in the nature of a foundation proper.

These considerations are of special importance at the present time, because recent developments point to the value of an ordinary waterbound broken stone crust, as what is called ' a foundation ' for a carpet of bituminous materials, or stone setts, wood blocks, or bricks; and it must be remembered that the extent to which the loads are spread by any of these carpeting materials is so small that the old crust should be brought up to its full strength, as a strength crust sufficient for the traffic. Further, in using materials with bituminous binders, it is possible to effect so good a bond with water-bound materials in the lower course that the whole thickness acts as one crust, the square of the depth of this crust being the measure of its beam or slab strength as well as of its effect in spreading the load as a cone. It is, therefore, very necessary that such a condition should not be confused with the condition when the wearing layer of relatively costly materials is quite thin, only thick enough to serve as a wearing carpet. There is a strong tendency towards the adoption of this plan, because the cost of making one set of materials quite effective in wear-resistance and another set effective in strength and resiliency tends to be less than that of using materials which have both qualities.

The Waterproof Carpet.

If a road-bed is so situated that no water will reach it from beyond the edges of the crust, and if a layer is spread over it, effective in preventing the access of water to it but not preventing the gradual escape of all moisture, the crust will become dry and be no longer water-bound. Tarred roads which are thus rendered very dry sometimes compare unfavourably as regards corrugations with other roads which have been less effectively waterproofed, or which are kept moist by the creep of water in the road-bed.

Water-bound Broken-stone Crusts.

In the ordinary water-bound, broken-stone road crust the wearing layer is simply the top part of the strength crust. Usually, the stone in this top portion is harder or tougher than that in the rest of the crust and differently graded, and it is therefore necessary to take care that the change in materials as the crust is built up from the first course of stone is not accompanied, at any stage, by the formation of a plane of division. There must be no hard surface and no parting layer within the crust when it is finished.

Binding Material.

One of the most frequent causes of the too rapid wear of both new crusts and repairs, especially repairs, is lack of sufficient binder. The use of too much earthy binder instead of a gritty binder, such as stone dust, is also a cause of too rapid wear. The former weakness, lack of binder, is, however, a much more serious and widespread weakness than is usually supposed, especially on secondary roads in some areas and by-roads and lanes in other areas. If no suitable binder is available when holes are filled with loose stones, it is better to use mud than to use nothing at all, and mud is better than dry earth, because the water comes to the top.

Segregation.

It is very necessary to avoid segregation. A mixture of stone and binder, supplied in the proper proportions, is ineffective, and fails to form a tough and durable crust if there are patches in which one size or another is in excess of its proper proportion. This applies also to the finishing of a road surface by filling considerable hollows with chips before the final rolling. The crust when finished should be practically mass concrete with its own true surface. The final touches should be of the nature of grouting, not rendering.

The Telford Road Crust.

In the case of a crust of the Telford type, in which large stones are placed with their lengths transversely to the road, the spaces packed with chips or gravel, and a layer of broken stone and binder formed over this, it is necessary either to treat the lower course as a foundation and to make the upper course adequate as the strength crust, or, which is usually better, so to form the upper course that its stones penetrate the gravel or chips of the lower course, and the whole thickness forms one strength crust. On very bad, wet ground the former plan is the better, that is, to treat the lower course as a foundation only, and make it not too compact for effective drainage.

Single Crust Roads.

In addition to the preceding notes, it may be pointed out that if the single crust is to have a fair chance of success, the road-bed should be carefully prepared. It should be brought to the correct shape, usually cambered, and it should be made of the same degree of hardness throughout, by ramming, and adding earth and ramming again, and, where necessary, by loosening before ramming. When a bottoming of gravel, or large stones, or a mixture of both, is used there should still be some preparation of the natural soil if it is of varying degrees of density; and it should always be brought to about the right camber. Otherwise, material is wasted, and the degree of resistance in the foundation varies, tending to the development of humps and hollows in the crust. Hollows in the road-bed should not be filled with the foundation material, but with material as similar as possible to that in the road-bed itself. Road crusts should *not* be thinner near the edges than they are in the middle part.

Footways.

Location.—Apart from the main engineering aspect the advantages of locating footways aloof from the carriageway are obvious. On new roads there should be a strip of turf of ample width between the footway and the carriageway. In recent cases, avenues of trees have been planted in such strips, but clumps of smaller growth, or hedges interrupted by clumps and by gaps, would, in many cases, be more appropriate and much more useful. Relatively small trees are valuable for this purpose, such as maple, Cornish elm, bird cherry; also dogwood and allied species.

Where width between fences is restricted, as in many cases of road improvement, overhedge footpaths offer many advantages, a narrow footway alongside the carriageway being provided where expedient. Such overhedge footpaths are usually very well placed in respect of drainage, but suitable cross drainage works should be provided where needed. The footpath should be given a considerable camber, or single cross slope, in most cases.

Construction.—The road-bed of a footway should be carefully prepared. A foundation of clinker (unless destructor or other hard clinker) or one of ashes, may be worse than useless. Only in rare cases is under-drainage of the crust necessary. The crust should be made with as much care as are the carriageways, preferably, as a rule, in the same way as a good broken-stone road crust, and with heavy rolling by a narrow roller, or a rammer. The softer classes of road metal provide the best materials. Most gravels are to be avoided. Cinders and ashes are

abominations. The material should, in any case, be graded, and contain no large lumps. The surface should be that of the crust itself; if dressed with tar or bitumen, the dressing should be applied sparingly. No gritting.

TAR MACADAM.

There are in ordinary use two ways of forming a bituminous-bound road crust. If the stone is coated beforehand with the tar, and allowed to stand until the coating is tacky, the crust can be 'consolidated' with a moderate amount of rolling. The extent of consolidation will partly depend upon the extent to which the stone is graded. As a rule, very little grading is regarded as necessary, the surface being closed by rolling in ¾-in. to ½-in. material. The other kind of crust, formed by 'pitch grouting,' usually consists of stone graded through a wider range, the smallest material being sand, added with the pitch, which is poured in hot. The surface is closed with small material. For tar macadam the 'general directions' issued by the Road Board advised at least 60 per cent. of 2½-in. stone and not more than 30 per cent. of 2½ to 1¼ in., the remaining 10 per cent. not being in the body of the crust but being used for closing (¾ to ½-in. stuff). For pitch-grouting, the sizes are: 60 per cent. of 2½ ins. and 35 per cent. of sizes *graded* from 2½ ins. to 1¼ in. In addition 5 per cent. of chips are to be used for closing after the pitch has been grouted in. The body of the crust will, however, contain a proportion of sand, equal, by measure, to that of the pitch. The quantity of pitch varies according to circumstances, but ordinary quantities, noted in the 'general directions,' are 1¼ gall. per sq. yd. for a 2-in. layer, 1½ gall. for a 2½ in. layer, and 2 galls. for a 3-in. layer.

The pitch used (Road Board specification) is to be thinned with tar oil in the proportion of 10 to 12 per cent. (of the whole). The pitch itself should not have more than 22 per cent. and must not have more than 24 per cent. of free carbon. The tar oil must have a specific gravity between 1·065 and 1·075 at 20° C. and must be commercially free from light oils and water.

Tar-macadam road crusts have been successfully made with stone of considerably smaller average sizes than the above.

Cost of Plant.—A plant at Stourbridge, including a 2-ft. revolving cylinder, 10 ft. long, inside a 3-ft. shell, and driven by a 5½ h.p. gas-engine, cost 350*l.*, and with it some 40 to 50 tons can be heated and mixed by three men in one day. The proportions of cost shown by a recently erected plant at Belfast are: broken stone and screenings, 60·67 per cent.; tar, etc., 11·49 per cent.; wages and cartage, 21·25 per cent.; tools, oil, etc., 1·94 per cent.; repairs and fittings, 4·65 per cent.

Limiting Gradient.—For ordinary tar macadam about 1 in 25 is regarded as the limiting gradient, but 1 in 30 or even 1 in 35 is sometimes preferred.

Cold Emulsions.—Emulsions of tar, of bitumen, or of both together, applied cold, are now being used to a considerable extent for both grouting and surface treatment. There are two kinds of emulsions, the natures of which have been studied. By one method there is produced an unstable product which, however, may be suitable if it is made for use on a specific job. By another process, or processes depending on one and the same principle, there is produced a material in which each particle of tar or bitumen is coated with a skin of some substance which isolates it, so that, for a very long time, the particles all remain suspended in the water without segregating. This is the kind to buy for general use. The material as supplied by the manufacturers is sometimes intended to be used neat, in which case two or more strengths may be supplied for grouting and for surface treatment. Other manufacturers supply a material which before use is to be mixed with water in a proportion depending on the purpose for which it is to be used. The former practice is likely to prove to be the better. These emulsions can be used for grouting and for surface work on damp or even wet crusts. A damp crust is better than a dry one, on the principle of the damp swab, resistance to penetration being less than when the materials are dry. If, however, a road crust is full of water it should be allowed to drain to a sufficient extent before being grouted. In the case of surface work it will be sufficient if the crust has begun to drain, being somewhat pervious, or if, it being impervious, water has ceased to drain from it and heavy rain is not immediately expected. Emulsions may, therefore, be used all the year round, saving in long periods of frost or wet. In the spring, summer, and autumn they may be used on many days on which the hot treatment is impossible. Their adoption must depend considerably on costs, but when the cost is higher than that with the hot treatment they may be used as a stand-by in order that work may be less often interrupted; thus, possibly, reducing the total cost or sparing the public from inconvenience. In grouting work the material, if not to be diluted, may be used directly from the barrel, which is then the unit related to road surface area; or it may be poured from cans. It is brushed into the road surface in order to effect an even distribution. The surface is then blinded with chippings which, as in other cases, should be of more even and somewhat smaller gauge than is usual in such work. The quantity to be used depends, as in the case of other grouting, upon the proportion of voids in the crust, and upon its thickness. If the crust is continuous and thicker than the depth which has to be grouted, precautions must be taken to prevent the absorption of too much emulsion per square yard. In the case of surface treatment, the procedure to be followed and the quantities per square yard may be found after a few trials by any person accustomed to hot tarring work. Before using an emulsion which is to be diluted, the latest information should be considered.

A special purpose for which cold emulsions may be used is that of gradually strengthening an absorbent road crust, by small doses repeated at intervals. No generally conclusive results have yet been obtained in this practice (1929).

SURFACE DRESSING

Including Treatment with Tar, taken as the Typical Case; with Bitumen; and with Mixtures of Tar and Bitumen.

General Policy.—At the present time the best results seem to follow the practice of tarring once a year only, except where the tarred surface is completely worn off before the autumn, and allowing the tar and some of the stony material of the crust to wear down by the winter. This prevents the road from becoming jolty and provides good foot and wheel-hold for the winter. Tar which remains below the surface is not harmful, but excess of tar, producing a greasy emulsion on a hard road, or thick, greasy mud in damp places, is to be avoided.

Conditions affecting Results.—Wind and free play for local air currents are needed to keep tarred roads cool. Roads exposed to wind and air currents will suffer little from sunshine; roads in airless places suffer much from sunshine. Roads in cuttings, and those flanked by walls and close palings, and especially if they run across the direction of prevailing winds, suffer from high temperatures in summer and from greasiness due to damp conditions in winter. Shade in itself is beneficial, both as regards the effects of sunshine and with respect to the frequency of frosts. Porous road crusts absorb more of the tar than impervious crusts, which reduces difficulties arising from high temperature or from greasy conditions. A dry and showery climate is much more favourable than a damp and drizzly climate, as regards both the work of tarring and the results obtained.

Cost of Tarring.—An ordinary cost is from 2*d.* to 3*d.* per square yard, in many cases about 2½*d.*, and in not a few well above 3*d.* In the year 1910–1911 the Buckinghamshire roads, 117 miles, cost ⅔*d.* per square yard. Main roads often cost about 150*l.* a mile per annum for tarring alone. One gallon of tar is usually sufficient for spraying 5½ square yards of road surface, and a gang of six men with a 320-gallon boiler will tar-paint 5,000 square yards in an ordinary day's work. For recent figures see p. 755.

Nature of the Tar.—Tar of the right consistency can be got by adding pitch to crude tar. It is better, however, to get the proper consistency by heating the tar until the lighter constituents are driven off, since their presence is in itself a source of trouble. The Road Board specifications describe two tars, No. 1 and No. 2, the latter which is the denser, for use only on warm, dry roads, and suitable for painting worn places. Tar No. 1 has a specific gravity of 1·16 to 1·22 at 15° C. (1·19 recommended). It must have not more than 1 per cent. of water and ammoniacal liquor. The free carbon should not exceed 16 per cent. by weight. Tar No. 2 has a specific gravity of 1·18 to 1·24 at 15° C. (1·21 recommended), and must be free from water. The free carbon should not exceed 18 per cent. by weight. Various bituminous preparations may be used instead of tar on most roads, except water-bound roads, for which tar is more suitable.

Some recent specifications allow as much as 21 or 22 per cent. of free carbon. In two such specifications, (*a*) and (*b*), the following are included: Products distilling at less than 100° C., (*a*) and (*b*) not to exceed 1 per cent; products distilling between 170° and 270° C., (*a*) 12 to 24, (*b*) 16 to 26 per cent.; between 270° and 300° C., (*a*) 4 to 12, (*b*) 3 to 10 per cent.

Method of Application.—The road should be dry and warm. The surface should be brushed hard to remove all dust and loose particles, the second brushing being in some cases done with soft brooms. The tar in the boiler should be at about boiling point, say 220° to 240° C. Its temperature when delivered on to the road will depend on the mode of application. Machines resembling water-carts do best on smooth roads which are true to shape. The spray, a fine rose at the end of a flexible tube, is used by hand, with the advantage that the quantity of tar applied to different parts may be varied if necessary. The spray is very effective in coating the stones with a clinging film, after which the required thickness can be sprayed on as desired. It works well on uneven roads. Tar can be successfully applied by hand, poured on and brushed in.

Blinding the Surface.—When the freshly tarred surface can be left for some hours undisturbed, this is usually done. On porous roads, or where the quantity used is small, it may be sufficient to blind this somewhat hardened surface with dust only; clean dust from the preparatory sweeping or destructor dust. In other cases, varying quantities of sand are added, or stone chips, the quantities and method of application depending upon the extent to which these materials are intended to form a mat with the tar, or to act as a temporary protection. Chips may crush to a kind of filling coat, or they may be used so as to form a definite mat. Sand may be added so as to form a mat, or may be strewn a little at a time so as to avoid the forming of a too sandy and brittle mat, but at the same time to act as a parting layer between the tar film and the wheels of vehicles. Some of the sand, if not removed by rain, may be swept off when the tar has hardened and the road is becoming dusty. The true granites are not amongst the best of materials for blinding the surface.

Hot Bitumen Treatment.—The preceding paragraphs apply, substantially, to treatment with hot bitumen. The choice of tar or bitumen may depend upon costs, the nature of the road crust, or personal preference. Some surveyors prefer tar for the treatment of water-bound broken stone roads. Tar is often preferred for the first treatment in French practice, bitumen for subsequent treatments. The Northamptonshire County Highways Committee concluded, 1928, that bitumen is more durable and ultimately less costly than tar, but that tarred surfaces

are less slippery ; the county surveyor might therefore, at his discretion, prefer tar, except near fisheries and streams.

Effects on Fish Life.—Tar is more likely than is bitumen to harm fish life if rain comes soon after it has been applied. Generally, if safeguards are not fully to be relied upon, bitumen is preferred to tar for roads the washings of which may pollute ponds or streams. It has been shown (*Butterfield*) that after the primary risk has passed or been avoided by applying the surface treatment in fine weather, ill effects upon fish or water-plant life may result from the hashing up of the treated surfaces and the wearing down of the material to a fineness such that it is washed away by rain.

Safeguards.—The chief safeguards are : suitable weather for the work ; use of pure materials, properly specified ; prevention of hashing up of the film ; passage of the road washings through settling pools or ditches and through filtering materials ; dilution with purposely diverted clean surface waters.

Dust.—There may be ill effects (*Butterfield*) from dust produced from surfaces treated with tar or bitumen, either as such or as material removed by rain after a dry spell.

Cold Emulsions (see under 'Tar Macadam,' p. 732).—For surface dressing, cold emulsions are largely employed, in direct competition with hot applications, in which case there may be reasons for preferring one or the other. Cold emulsions can also be used, with full efficiency, when the roads are damp and, at the discretion of the surveyor, in rainy weather. In Herefordshire cold emulsions are used for the constant repairing of potholes (*G. H. Jack*); all noticeable potholes having disappeared after 12 months of this work.

SLIPPERINESS.

Some of the work done recently, on main roads especially, has produced very slippery surfaces. In some cases the road is regarded as dangerously slippery except when quite wet or quite dry, while there are some roads which are not satisfactory under any weather conditions. In the case of a surface which is, in the ordinary course, tarred from time to time in order to preserve it, it may be desirable to incorporate finely crushed flint or quartz with the tar ; in other cases the rolling in of crushed flint in hot weather may be desirable. The treatment depends upon the nature of the crust or carpeting, and no general directions can be given. To prevent slipperiness by a suitable choice of materials and methods, care should be taken to avoid unsuitable grading, the use of too much very smooth stone in the aggregate, the use of an unsuitable bituminous or asphaltic binder, and, generally, the employment of materials which either separately or in combination tend to form a grease under traffic. The crust or carpet should be reasonably resilient, a surface which rings musically under blows being avoided.

Very good results in producing non-slippery surfaces have been reached by Mr. E. J. Lovegrove, who puts down crusts of a carefully graded aggregate of crushed destructor clinker, the bituminous binder being made of a substance having a somewhat low 'penetration,' under the usual test. The materials should be so chosen and so compacted that they will not wear too slowly. In the case of water-bound roads it has been found necessary to use a very gritty binder of siliceous material in order to correct the tendency towards the formation of a greasy slime, which is a feature under road conditions, of some limestones and most granites, including all true granites.

Non-Slippery Road Crusts.—Non-slippery road crusts can be made in the tar macadam and tar-slag macadam classes, using coated material or grouting with hot or cold preparations. Also in the cement grouted class, with a fairly wide range in the choice of stone and using rapid-hardening cement.

See p. 753, 'Gladwell System.'

Silicated Roads.—Another class, of growing importance in this and other respects, is that of silicated roads—that is to say, roads in which the sodium silicate effects the binding of the whole crust. This method seems to be at present restricted to areas in which soft limestone is available, but it may be found worth while to modify it by importing the necessary proportion of such material to bind other stones. The French engineer Jacques-Thomas found that the proportion of silica to soda, initially 3·15 in a solution, was reduced by penetration into a piece of limestone after 24 hours soaking ; at 1 to 2 cm. within the stone, 3·0 ; between 2 and 4 cm., 2·9 ; between 4 and 6 cm., 1·5. (For data relating to the method, see p. 742.)

Rubber Mud.—After a long spell of dry weather on roads in Norfolk (S. H. Warren) skidding was frequent. The dust formed during the dry spell was analysed and found to consist largely of rubber, which formed a greasy mud with the water of the first shower.

The remedy for this would seem to be to sweep the roads at threat of rain after a long, dry period.

To reduce the effects of collisions due to skidding, there has been introduced the policy of providing guide posts which snap off very near the ground if struck hard by a vehicle. The principle, inversely stated, is that of refraining from putting up resistant fences or walls, instead of ordinary hedges, at dangerous bends and turnings. The guide posts, which are the first on this principle, have been designed for the R.A.C. and accepted by the Minister of Transport.

CONCRETE ROADS.

As regards country roads of ordinary width serious difficulties in the use of a concrete crust which is also the wearing layer, are: the necessity for allowing time to set; the practical difficulty in keeping one-half of the road closed for a month or more; and the resulting joint of hard to fresh concrete.

Alternatively, there is the difficulty, both in law and fact, of completely closing a road in long stretches for a period of a month *plus* the time it takes to get through with the concreting of the stretch of road in question.

The use of one of the rapid hardening or high alumina cements (such as 'Ferrocrete' and 'Ciment Fondu') with which rapid hardening concrete can be made has overcome this difficulty, and concrete strength crusts for arterial and by-pass roads are steadily growing in favour. The naked concrete road crust, though regarded as experimental in many specific cases, must now be considered as competing with other kinds of road surfacing.

Generally.—The weakness of joints, as regards strength and wear, is one of the chief difficulties in the adoption of the concrete wearing crust. It has been found that joints become 'frayed,' and open up. As in the case of strength crusts of concrete under paving or carpeting, the whole crust of concrete suffers from the effects of street openings and local repairs, but in a greater degree. These difficulties are not insuperable, but they are serious especially as regards country roads.

When joints are not provided, or are insufficient, concrete roads crack very badly, as has been the case to a large extent in the United States.

REINFORCED CONCRETE ROADS.

When the slab is definitely a foundation, under a strength crust, light reinforcing is sufficient and usually single reinforcement. In this case the lengthwise reinforcement may be more than the crosswise reinforcement in order to prevent the forming of temperature cracks across the road. When the slab is to be the strength crust, or the principal strength crust, double reinforcement is usually to be preferred, and in most cases is the proper method structurally. When the purpose of the slab is to extend the supporting area of an insufficiently firm but equally resisting foundation, the lower reinforcement may be stronger than the upper—more or thicker rods. When the purpose of the slab is to combine the unequal resistances of different parts of an unequally resisting foundation the upper and lower reinforcement should be about equally strong. Because the little piece of the slab under the wheel is supported from athwart the wheel as well as from fore and aft, the slab should be reinforced across the road about as strongly as it is along the road. Because a wheel close to the edge of the road slab is unsupported from one side, the slab must either be reinforced as a cantilever near the edges, or the lengthwise reinforcement must be increased to the actually necessary extent by closer spacing of the rods. There are alternatives, applicable under special conditions, such as extending the slab under the footway, or converting the edge of the slab into a kerb with the proper reinforcement in the vertical plane. When the calculations show that it it demanded, there should be diagonal reinforcement in the vertical planes of a road slab. A reasonable base should always be provided on very soft or treacherous ground, including otherwise firm ground which may suffer denudation by the action of trickling water. A slab cannot float as a raft nor sustain its own weight and the live loads if the average resistance of the soil is unequal to these. A slab provided with parapets, of a piece with it, may, however, be worth considering as a means of carrying a road across a bog.

Depth of Slab.

Much thinner slabs than those usually employed would be theoretically sufficient in most cases, and usually more economical of materials, but practically it is found to be better to have thicker slabs for the following reasons: (*a*) With a deeper spacing between the upper and lower grilles, less steel is needed, the mesh can be larger, larger stones may be used in the aggregate, and the filling in of the concrete is done more easily. (*b*) Any fairly large piece of road metal, left accidentally on the foundation or in the aggregate, may lead to the formation of a tension crack on the under side of the slab. (*c*) In some cases the depth which must somehow be filled is not sufficient to make it worth while to provide a firmly rolled hard-core foundation, the cheaper solution being to employ a relatively low-stressed slab, with a somewhat reduced proportion of cement and relatively light reinforcement. (*d*) Lastly, 7 ins. of fairly tough concrete, with large-mesh reinforcement, is more easily cut through, for excavations, than 4 ins. of very tough concrete with a smaller mesh reinforcement.

The advantages of having two layers of reinforcement are now being recognised, the value of the steel in two layers being greater than that of the same quantity in one layer. In some cases there is also reinforcement in vertical planes: an example of this being vertical triangular reinforcement, between an upper and a lower grille, in Paddington.

NAMES OF ROCKS USED FOR ROAD METAL.

When a single word is employed as the name of a rock used for road metal or for paving setts the word may be definite in itself, denoting a rock of a particular composition which does not, as a rule, vary much from the average. In other cases, the general word, or word denoting the normal material, is compounded with another word, usually the name of a mineral which is present in an unusually large proportion, or which is an unusual constituent or one of several, any of which may be present. Thus, a diabase is usually composed chiefly of labradorite and augite, and sometimes olivine; and dolerite, though different in texture, is similar in composition. An olivine dolerite is a dolerite in which olivine is present in a considerable proportion, and a quartz-enstatite diabase is a diabase in which both quartz and enstatite (minerals, not rock names) are present in noteworthy proportions.

The following classification was suggested some years ago (*vide* 'The King's Highway') as a tentative grouping. It is here slightly altered.

Granites: True granites, horneblende granites (micro-granites).

Felstones: (*a*) Basaltic felstones:—Basalts, diabases, dolerites.

(*b*) Hornblendic felstones:—syenite, diorite, quartz-syenite, quartz-diorite.

Traps: (*a*) Whinstones—basic traps.

(*b*) Elvans—acid traps, quartz-felsites, quartz-porphyries (micro-granites).

Quartzites: both metamorphic and sedimentary.

Limestones: compact limestones, crystalline limestones.

Rags: calcareous sandstones, siliceous limestones.

Sandstones: true sandstones, grits.

Flints: flints, chert.

Pebbles: large broken pebbles to be named according to their class, small pebbles classed as gravels.

SOME IMPORTANT WORDS IN THEIR NARROWER APPLICATION.

The following are definitions of certain important rocks:—

Granite.—A coarsely-grained, wholly crystalline rock, mainly composed of alkali felspar, quartz, and a ferro-magnesian mineral.

Gneiss.—A metamorphic (altered) rock, usually resembling granite, but showing a foliated or banded structure.

Syenite.—A wholly crystalline rock, composed of orthoclase felspar, a ferro-magnesian mineral (usually augite or horneblende), and a small proportion of quartz.

Diabase.—A compact, dark rock, mainly composed of labradorite, augite, and sometimes olivine; is thoroughly crystalline and often ophitic (ophitic: a structure in which the crystals of one mineral inter-penetrate or are moulded upon those of another).

Dolerite.—Often classed as basalt, or as diabase. (The terms 'diabase' and 'dolerite' are often used synonymously.) Is more crystalline than basalt.

Diorite.—Consists essentially of oligoclase, andesine or labradorite felspar, and horneblende, augite, or biotite.

Basalt.—A black compact lava, basic (alkaline) in character. Consists essentially of plagioclase, augite, and olivine, is sometimes porphyritic, and often contains uncrystallised glass substance in the ground mass.

Porphyry.—Contains large crystals, usually of potash-soda felspar, in a ground mass of felspar, quartz, and other minerals.

Andesite.—A lava, intermediate between acid and basic, consisting principally of plagioclase, felspar, and ferro-magnesian minerals, usually without olivine.

Quartzite.—Composed almost entirely of close-fitting quartz grains, the cementing material being itself quartzose, distinguishing it from sandstones.

Whinstones.—In its narrower and more correct use the term is applied to dyke or trap rocks. A typical whinstone may be classed as an andesitic dolerite, containing augite, or as a quartz diabase.

Bituminous Macadam Roads.

(Abbreviated from a description by A. W. Dean, Chief Engineer, Massachusetts Highway Commission.)

A gravel, or suitable sand, foundation may not be needed. If a stone foundation is made on a clay subsoil, the interstices should be filled with gravel to prevent the clay working up, but if one is used care should be taken to use suitable materials, especially the gravel (see p. 389).

First course.—The thickness of the first course, of broken stone, depends on local conditions. For instance, if a 10-in. foundation is necessary, the first course of the crust need only be about 2 ins. thick. If no foundation is necessary, the first course of the crust should be not less than 4 ins. after rolling, or 6 ins. for heavy loads. The stones of this course may vary from ½ in. to 3 ins. in longest dimensions, but the percentage of the small size should be very small. For a course of 4 ins. or less a good size is 1½ ins. to 2½ ins. In a 6-in. course the maximum size may be 3 ins.

The voids must be well filled with fine material to prevent loss of bitumen from the upper course. The surface must be even. All surplus dust and fine material must be swept off, leaving the upper stones bare to receive the second, or bituminous, course.

Bituminous course.—The second, or bituminous, course to be 2 ins. thick, or 3 ins. for heavy vehicles in large volume. The stone must be of good quality and uniform in character, and the sizes not segregated. The best results are obtained with stone from ¾ in. to 2½ ins., the larger sizes predominating, although the course be only 2 ins. thick. The rolling should be thorough.

Application of bituminous material.—This is applied at a temperature of 250° to 300° F., with a mechanical distributor, with a force equivalent to that obtained under a pressure of 30 lbs. per square inch, or more. The amount per square yard is from 1¼ gallons on a 2-in. course to about 2 gallons on a 2½-in. course. It should be very evenly spread.

Surfacing.—The surface should be lightly but completely covered with pea stone (½-in. stone) and thoroughly rolled with a 15-ton roller, if available, and if the stone is of hard quality, and a lighter roller for a poor quality stone.

Seal coat.—A seal coat of the same quality of bitumen is applied, half a gallon per square yard, covered with pea stone, and finished off with a heavy roller. When the bitumen is applied the stone must not be wet but may be moist. It must be clean and free from dust.

Bituminous Carpeting.

(Abbreviated from a description of work carried out in Kent. County Surveyor of Kent, H. T. Chapman, M.Inst.C.E.)

The work is done in two operations. The base coat of local stone, flint, scarified material, or clinker, mixed with bituminous material, is laid hot to form a nearly voidless concrete, not less than 3 ins. thick. For the carpet, sand, grit, or selected crushed clinker is graded between a 200 and a ¼-in. mesh and mixed with from 13 to 15 per cent. of bituminous material, and laid at a temperature of 300° to 350° F.

In a specific case, 1914, the base coat was 3 to 4 ins. thick, of crushed shingle and flint, 1½-in. to ½-in. gauge, coated with a pitch and tar mixture, 8 parts soft pitch to 3 parts tar. The carpet was 1½ ins. thick, of grit 31 per cent., sand 56 per cent., and bitumen 13 per cent. All these ingredients were heated to 350° F. and mixed. The carpet was first cross-rolled and then consolidated with a 10-ton roller.

Costs.—Costs were, base coat, 2*s.* 6*d.*, carpet, 2*s.* 7*d.*, total, 5*s.* 1*d.* per square yard, the prices of the materials being at practically pre-war rates.

The results have been very satisfactory.

According to the remarks of several speakers at a meeting of the Institution of Municipal and County Engineers, asphalt macadam, as a wearing surface for roads should be laid in one coat. It can apparently be laid in one thickness of 3½ ins. quite satisfactorily, whereas if put down in two layers the upper part creeps or peels off under traffic.

Concrete Roads, Including Wearing Surface.

Chelsea Embankment.—Much traffic, including very heavy vehicles. A naked concrete roadway, in slabs about 50 ft. long and 4 in the width of the carriageway. Upper and lower grille reinforcement. Lengthwise joints formed by laying fresh concrete against hardened concrete, and run with bitumen. Narrow transverse space joints filled with bitumen. Fine cracks appeared in a few slabs in the first cold weather after placing the concrete. These gave no trouble except where across the sharper than right-angle corners formed by the skewing of the transverse joints, but this tendency to breaking off of the corners was checked by the use of bitumen, which has also been used to protect all joints and cracks. No other maintenance measures needed. Condition very good after 40 months, slight depressions at a few corners, but no further breakage. One of the best surfaces in London.

Steel-Mesh Road Reinforcement (Proprietary).—A series of metal strips bent into zigzag shape, laid on edge, side by side, and locked together by means of pins into a continuous mat of steel squares. Has been used on a tramway route in Birmingham. Is expected to be useful at omnibus stopping places. Imbedded in naked concrete at certain spots on Chelsea Embankment, its value cannot yet be estimated because that concrete crust is, so far, generally in good condition; but no signs of the steel-mesh doing any harm can be seen.

Life of Concrete Road Crusts.—New King Street, Deptford; laid 1917; 9-in.; double reinforcement; heavy traffic; in serviceable condition, 1927. Tilbury Dock Road: laid in 1917, in alluvium; 7-in.; single reinforcement; in good condition, 1927. Canmore Street, Dunfermline: laid 1916; in satisfactory condition, 1927. Southwark: 130 roads and streets laid since 1918 give satisfaction. Main Bridgewater Road, laid 1920: no expenditure on maintenance and very slight signs of wear, 1927.

Points from Ordinary Practice.

When making a reinforced concrete road slab in half-widths at a time, the transverse rods of the first half must be left projecting sufficiently to be effectively bonded into the second half. Unless there is a considerable margin of strength, the weakness across the middle line should be countered by providing additional lengthwise reinforcement on each side of it. The road-bed should be drenched before the concrete is laid. If it be clay, or a clayey soil, hard-core should be rolled in. The concrete must not be in the least sloppy; if excess water be removed by rolling, this should be done transversely, with a light roller. If the slab provides the wearing surface a tamping finish may be sufficient, and floating should be done very sparingly; the belt finish is better. The concrete should be protected by a tarpaulin for a day or two, and, anyhow, be amply protected from frost. It should be matured by waterings for ten to fourteen days, and not opened to traffic for two or three weeks under very favourable conditions, being kept closed for much longer periods under ordinary or adverse conditions. For the sake of economy of concrete the road-bed should be brought to the same camber as the surface. The proper proportions for the concrete can only be decided by the designer, but in order to provide a starting-point for the calculations, it may be noted that a fairly ordinary proportioning for slabs of about 6 ins. in thickness is 1 : 2 : 4, with 1 : 1¾ : 3 for the surface, or, if the fine material be graded from ¼ in. to dust, 1 : 1½ : 3 throughout. Reinforcement should be accurately placed in position before concreting, and should be, preferably, not more than 2 ins. nor less than 1½ in. from the surface or bottom of the concrete. On clay soils a bottoming, such as clinkers, should be provided, and, generally, a suitable bed prepared for the concrete. Expansion joints should be provided at intervals of 50 ft. or less if the slab is reinforced, or at not more than 30 ft. if it is not reinforced.

Analysis of Costs.

Billingham, urban district (*G. H. Hill*).—Main roads on building estate; shillings per sq. yd., stripping, forming, and laying ashes, manual labour, 1·57; team, 0·61; concreting the carriageway, manual labour, 1·03; team, 0·11; cement, 1·59; gravel, 1·91; reinforcement, fabric, 0·84; petrol for mixer, 0·04; hire of mixer, 0·25; use of tools, 0·12. Total, 8·07 shillings per sq. yd. of the 6-in. slab of 1 to 6 gravel concrete.

Drying and Mixing Plant.

The principal essential parts of a Standard Plant are: (1) elevating skip, (2) drying drum or drums, (3) furnace, (4) flue and fan, (5) mixer, (6) driving pulley and gear, and (7) underframe, which also forms the operating platform. The plants can be hauled from place to place by a steam-roller or traction-engine, and they are almost invariably belt-driven by the same engine—a pulley being fitted for the purpose.

The smaller portable plants (Urban and No. 0) are sometimes fitted with a direct-coupled petrol engine, mounted on a platform, but the largest portable plant (No. 1) is driven by a separate power unit—usually the tractor that hauls it. The stationary plants are invariably belt-driven by a separate steam, petrol, or gas engine or electric motor though a direct-coupled power unit could be fitted to the platform if required.

The aggregate to be dried is either fed by chute direct into a fixed measuring hopper or shovelled or tipped into the skip, which measures a definite batch. The skip is hoisted by power, strikes the auto-knockout gear, and quickly and cleanly discharges the whole batch into the fixed receiving hopper without spilling.

In the Urban plant this receiving hopper has a counterbalanced door which automatically opens and passes the batch into the drying drum and then closes again. This means that once an Urban batch has been discharged from the skip, it must pass into the drum. On all the larger sizes the door of the receiving hopper must be opened by a hand lever, so that a batch can be kept in the receiving hopper any length of time, thus making it possible for *five* separate batches to be handled by the plant at the same time—one each in skip, receiving hopper, drying and heating drums, and mixer.

From the receiving hopper the batch is passed into the drying drum or drums; then, when all the moisture has been evaporated and the aggregate heated to the required temperature, it is

passed by hand lever into the mixer, from which, after being *visibly* thoroughly coated with the hot binder that is poured in, the whole batch is discharged into the receptacle beneath.

The Urban plant takes 12 to 15 b.h.p., which is ample to drive the plant and any auxiliary equipment, such as a tar or bitumen pump.

TABLE V.

APPROXIMATE AVERAGE OUTPUTS PER HOUR OF TAR AND BITUMINOUS MACADAM, GIVEN BY BATCH-TYPE COMBINED DRYING AND MIXING PLANTS.

Type of Plant	Portable or Stationary			Stationary only	
No. of Drying Drums	Single Drum	Double Drum		Double Drum	
Size of Plant	Urban	No. 0	No. 1	No. 2	No. 3
Batch Capacity	6 cu. ft. or 0·17 cu. metres	6 cu. ft. or 0·17 cu. metres	11·5 cu. ft. or 0·33 cu. metres	18 cu. ft. or 0·5 cu. metres	27 cu. ft. or 0·76 cu. metres
Tar Macadam :—	Output per Hour.	Output per Hour.	Output per Hour.	Output per Hour.	Output per Hour.
2½ in. . . 5·7 c.m. . .	4 tons or 4,064 kilos.	6 tons or 6,096 kilos.	12 tons or 12,192 kilos.	16·5 tons or 16,764 kilos.	24 tons or 20,400 kilos.
1½ in. . . 3·8 c.m. . .	3·5 tons or 3,556 kilos.	5 tons or 5,080 kilos.	10 tons or 10,160 kilos.	14·5 tons or 14,732 kilos.	22 tons or 22,352 kilos.
¼ in. . . 0·635 cm. .	3 tons or 3,048 kilos.	4·5 tons or 4,572 kilos.	9 tons or 9,144 kilos.	12 tons or 12,192 kilos.	19·5 tons or 19,812 kilos.
Bituminous Macadam	*Up to about 25 per cent. less than above figures given for Tar Macadam.*				

The above output figures are based on aggregate weighing 100 lbs. or 45 kilos. per cu. ft., and an output of one batch every 2½ minutes.

BRICK ROADS.

(By Alfred B. Searle, Author of 'Clays and Clay Products,' etc.)

Bricks used for roads should be so hard and tough that they will resist the crushing, vibration and abrading actions of the traffic. They must be made of suitable materials, such as marls and shales, which yield dense, heavy and impervious product when burned. The clays used for common building bricks are quite unsuitable, being too readily disintegrated. Bricks for roads should consist of a tough skeleton, the interstices of which are filled with a tough slag-like mass of great viscosity when molten. When broken, such bricks show a dull, glassy structure, not readily affected by vigorous blows from a hammer. The modulus of rupture R should be at least 1,500 lbs. per sq. in. It is determined by supporting a brick on two knife edges 1 in. apart, and applying a pressure or load of W lbs. by means of a central knife edge. If the brick is b in. wide and d in. deep,

$$R = \frac{3Wl}{2bd^2}.$$

As bricks vary considerably, the test should be made on at least six bricks. When ten bricks are placed in a rattler with 10 cub. in. balls each weighing 7½ lbs. and 245–260 smaller balls of 1 lb. each (making a total of 300 lbs. of balls) and the rattler is rotated 1,800 times at 30 revs. per min., the pieces of brick more than 2 ins. diameter should not weigh less than 75 per cent. of the original weight of the bricks.

The size of bricks used for roads is of minor importance, provided that all the bricks used on a job are sufficiently uniform, i.e., with a variation of not more than ¼ in. in length and ⅛ in. in depth and width. The size usually preferred is 9 ins. by 4½ ins. by 3 ins.

The best results are obtained by using bricks with lugs (A, A, figs. 1 and 2) and a double bevel or bulge of $\frac{3}{32}$ in. at each end to ensure a joint at least $\frac{3}{16}$ in. wide at the top and the bottom of the brick. These are no more expensive to make and they 'key' better than plain bricks. *Pressed* bricks should not, as a rule, be used for roads, as they are less durable than those made by the wire-cut process. Bricks should be laid with the rough, wire-cut sides vertical and in contact with the filler so as to ensure the latter being retained properly. This is almost impossible with the smoother surface possessed by pressed bricks.

The *foundation* of the brick road must be good and well drained. A 1 : 3 : 6 concrete foundation 6 in. thick is best, but an old macadam road, if well graded and rolled, is satisfactory.

The *cushion* or *bedding course* may be of (i) sand, (ii) sand and dry Portland cement, or (iii) mortar. A *sand bed* should not be more than 2½ ins. thick and consist of uniform grains, and the sand used must be quite dry. It may be consolidated by rolling under a pressure of 15 lbs. per sq. in. A *cement-sand bed* should consist of 1 part of dry Portland cement to 3 parts of sand, well mixed in a dry state and spread on the foundation to a thickness of ½ in., any surplus material being removed with a straight-edge. This bed must not be rolled. The bricks are laid dry on this cushion and are then saturated with water so as to cause the cement beneath to set.

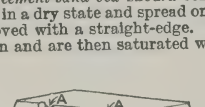

FIG. 1.

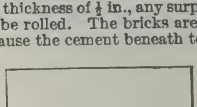

FIG. 2.

The *joints* should be filled with a 3 : 4 mixture of Portland cement and sand, the latter passing completely through a No. 20 sieve, but being wholly retained on a No. 100 sieve. The cement and sand should be mixed in the dry state, the mixture delivered to the road and mixed with water in a concrete mixer as required. The resultant slurry should be received in spouted cans and poured from these in a thin stream between the joints of the bricks, the fluid being well brushed into the joints. Two or even three applications of slurry may be needed, and are better than filling the joints at once. The second and subsequent quantities of slurry should be more viscous than the first one, and between each application any surplus slurry should be pushed (not drawn) into the joints with a rubber squeezer. The men should not walk or stand on the finished roadway when at work.

Maturing is effected by covering the road with sand which is kept well wetted for several days, so as to allow the cement to set properly. If this precaution is not taken the cement will be weak through a deficiency of water. The sand then may be allowed to dry, after which it can be used on another section of the road.

The road should not be used until three weeks after filling, as if the grouting is disturbed before it has hardened sufficiently the joints will be weak and the road will not be durable. If a road must be open for traffic in a much shorter time, a cement filling is little or no better than plain sand which is merely brushed into the joints, a small surplus being left on the surface of the road to be worked into the joints by the traffic; or a hot mixture of tar and sand may be poured into the joints. If time is less important, the cement-filled joints are far the best.

NOTES ON BRICK ROADS.

Experiments are being made in London with the surfacing of concrete road foundations with bricks, in order to carry heavy road traffic. The first bricks supplied from France for this purpose were laid in October 1927 at the Great Western Railway, Westbourne Park Goods Yard, and the entrance to the Municipal Depot of the Chelsea Borough Council has now also been paved with these bricks. In all cases the bricks will be subjected to exceptionally heavy traffic.

The bricks used are reddish-brown externally, while the interior is blue or mottled red. They are tough and strong, heavy and compact. Their weight is, on an average of ten bricks, 136·5 lbs. per cubic foot, and their absorption is less than 1 per cent. When laid on the flat and crushed, they split vertically, and have as high a crushing strength as first-class Staffordshire blue bricks. The characteristics which make them particularly suitable for road surfaces are: (1) Regularity of shape and size; (2) an even grain at right angles to the wearing surface; and (3) a texture which affords a firm foothold.

The method of construction which has been found to be most satisfactory, according to experience in France, is as follows: Fine, damp sand, free from small stones, is laid on a properly-cambered and matured concrete foundation. The sand is screeded to a uniform depth of ¾ in., and then pressed down by hand. The bricks are laid on this, as close as practicable to one another, in the manner of wood-block paving. They are then rolled by a three-ton roller. If any of the bricks break under this treatment, they can be pulled out quickly by a special pair of tongs and replaced by others. The joints are then filled with Texaco, or some other suitable asphalt, at a temperature of 350° F. This is poured in from a melting kettle. An alternative

method is to use a grout made with quick-hardening cement for the joints. Traffic can be allowed on the road a few hours after the asphalt joints are finished, or in a few days when cement is used.

Brick paving is used to a considerable extent in the United States, where both bitumen and cement filling have been used. While the former has mostly proved satisfactory, the latter has, under certain climatic conditions, proved quite unsuitable, actual explosions of paving having occurred, with considerable damage to passing traffic.

The following conclusions have been drawn as the result of tests made by the United States Bureau of Public Roads: (1) Bricks should be bedded on sand in preference to a cement-sand bed. (2) The thickness of the bricks should be at least 2½ ins. and, to allow for wear, should be preferably thicker. (3) The super-elevation on curves should be sufficient for a reasonable speed in order to prevent excessive wear on the track by the outer wheel. (4) Considerable care should be taken to obtain suitable vertical fibre bricks of high strength and uniform quality.

It is generally considered that this class of work is suitable for heavy traffic and where renewals must be effected quickly. The fact that some two million square yards of this type of paving have been laid in the United States since 1905, and that it continues to be adopted, indicates that it has been found to be satisfactory.

POINTS FROM SPECIFICATIONS.

From Road Department Specifications.

(The first six paragraphs apply to the re-surfacing of water-bound macadam.)

Thickness of Crust.—On a good natural foundation, old and new crusts together not less than 4 ins.; nor under ordinary circumstances less than 5 ins.; on yielding subsoils not less than 9 ins. New coatings of more than 3 ins. should be applied in two courses, separately rolled.

Cross-fall.—The finished surface should have a cross-fall of 1 in 24.

Stone and Screenings.—The stone should be broken as cubically as possible. About 70 per cent. should pass through a 2½-in. ring, and not through a 1¾ in. ring. About 20 per cent. should pass through a 1¾-in. ring, but not through a screen with rods ¾ in. apart. The screenings from this screen should be kept for top-dressing.

Rolling.—The roller should weigh about 10 tons, and be worked from the sides towards the centre, the correct cross-fall being attained before adding water or binding.

Binding.—The binding should be the best obtainable. It should be either of the same material as the new coating or of granite, limestone, or slag chippings, or failing these, suitable pit-sand or gravel, and the largest stone in it should not exceed ¾ in. in its greatest dimension.

Re-rolling.—In some cases it is advisable that a steam-rolled water-bound macadam surface should be lightly watered and re-rolled from a week to a fortnight after the first rolling.

Surface-tarring a Water-bound Macadam Road.—The road should be scraped or brushed in the early months of the year, in wet weather. Tar No. 1., Road Department Specification, should be used and be heated to between 220° and 240° F. The spouts of pouring cans should be not less than 1½ inches in diameter at the orifice. A gallon should cover from 5 to 7 square yards. Delay before gritting is advisable. On roads with heavy traffic it is desirable to tar the road again, or a central strip of 9 to 12 ft., two or three months after the first tarring; a gallon to cover 8 to 10 square yards.

Pitch-grouted Macadam.—The finished thickness should be 2½ to 3 ins., or on very light trafficked roads 2 ins., for single grouting, and 4 to 4½ ins. for double grouting. The cross-fall of the finished surface should be 1 in 32. Of the broken stone aggregate, 60 per cent. should be 2½ ins. and 35 per cent. graded 2½ to 1½ ins. For closing down after grouting, 5 per cent. of chippings, ¾ to ⅜ in. The pitch to comply with the Road Board Specification, the quantities applied being: for a 2-in. coating, 1½ gallon per sq. yd.; for a 2½-in. coating, 1⅔ gal. per sq. yd.; for a 3-in. coating 2 gals. per sq. yd., but the quantities needed may vary, and the voids must be filled. The pitch must be raised to a temperature of 300° F. and the sand to 400° F., and the matrix formed by mixing the pitch and the sand in equal parts, and kept stirred till it is poured. The final rolling to begin immediately after the pouring of the matrix and carried on rapidly. The 5 per cent. of graded chippings should be spread in part previously to the rolling, and the remainder during its progress.

Double Pitch Grouting.—The lower layer should be the thicker and consist of large stones, 3-in. to 2-in. gauge; a cheap local stone suitable for foundation work may be used. No chippings are required for the bottom layer. The upper layer aggregate of hard road stone 1½ in. gauge. The chippings should be graded from ½ in. to ¼ in. The quantities of pitch required are 3¼ gals. per sq. yd. for 4-in. work and 3½ gals. for 4¼-in. work.

Points from other Specifications.

Clinker Asphalt Paving (Sheffield: Mr. W. J. Hadfield).—Hard-burnt destructor clinker is used, crushed and screened; ½-in. mesh for the bottom coat and ¼-in. mesh down for the top coat. The rejections are used for ordinary tar macadam. The material is heated to 300° C. There is about 10 per cent. bitumen in the bottom coat and 17 per cent. in the top coat. The bottom coat is spread to rather more than 1 in. in thickness and slightly rolled. The top coat has a thickness of rather less than 1 in. when rolled, giving a total of 2 ins. Rolling is continued till no further impression can be made on the material. A 12-ton roller is preferred.

Manufactured Asphalt (A) ('Highway Engineering,' Blanchard and Drowne).—This is a combination of native bitumen and refined asphaltic oil. Specific gravity at 25° C. between 0·965 and 1·000. Ninety-nine per cent. soluble in carbon disulphide. To contain between 18 and 25 per cent. of bitumen insoluble in 88° Baumé paraffin naphtha. Between 5 and 10 per cent. of fixed carbon. Penetration between 150 and 200, with a No. 2 needle, weighted with 100 grammes; 5 seconds, 25° C.

Manufactured Asphalt (B) (Blanchard and Drowne).—This is manufactured by fluxing a refined native bitumen. Specific gravity 1·010 to 1·045 at 25° C. Ninety-two per cent. soluble in carbon disulphide. Between 18 and 25 per cent. of bitumen insoluble in 88° Baumé paraffin naphtha. Between 9 and 13 per cent. of fixed carbon. Penetration 100 to 200, with a No. 2 needle, weighted with 100 grammes; 5 seconds, 25° C.

Asphaltic Carpet.—British report to Fifth International Road Congress; type specification; bitumen soluble in carbon disulphide, 12 per cent.; aggregate passing: 200 mesh, 17; 100 mesh 15; 80 mesh, 15; 50 mesh, 25; 40 mesh, 8; 30 mesh, 4; 20 mesh, 2; 10 mesh, 2 per cent.

Granited Rock Asphalt.—(Same report): Type specification of gauging; fine powder, passing 100 mesh, 30 to 40; passing 50 mesh, 20 to 30; passing 30 mesh, 10 to 20; passing 10 mesh, 5 to 15 per cent.

Single-coat Asphalt-Macadam.—(Same report): Type specifications; (*a*) 3-ins. thick on poor foundation for moderate traffic; 1-in. stone, 35; ½-in. stone, 35; graded sand, 18; filler (such as Portland cement), 5 per cent.; bitumen, 7 per cent.; (*b*) 2-ins. thick on sound foundation for heavy traffic; ½-in. stone, 33; graded sand, 45; filler, 10; bitumen, 12 per cent.

Two-coat Asphalt-Macadam.—(Same report): For total thickness 3 ins.; binder course 2¾-ins., wearing course 1-in. Binder course, bitumen 5, sand 15, broken stone all passing 1½-in. ring and not more than 5 per cent. passing 10 mesh sieve, 65 per cent.; wearing surface, all passing ⅜-in. mesh sieve; passing 10 mesh and retained on 40 mesh, 10 per cent.; 40–80 mesh, 20; 80–200 10; passing 200 mesh, 12; bitumen soluble in carbon disulphide, 10·5. For 4½-in. total thickness as above, but 3½ and 1½-in. courses; binder course, 7 per cent. bitumen; sand, 25 per cent.; the broken stone, 85 per cent.; wearing surface, all passing ⅜-in. mesh; 10–40 mesh, 35; 40–80, 55; 80–200, 30; passing 200, 20 per cent.

Concrete Road Crust.—Epsom R.D.C., Class B road, 2,752 tons per day; reinforcement to have ultimate resistance across the road of 12,500 lbs. per foot; slab, 7 ins. of shingle concrete finished with 2 ins. of granite concrete; shingle portion: aggregate, by weight, 54 per cent. passing 1½ to ¼-in. square mesh, 24 per cent. passing $\frac{5}{16}$ square mesh, 22 per cent. passing $\frac{3}{16}$ mesh; sand, all passing $\frac{3}{16}$, not more than 5 per cent. passing 100 mesh sieve; cement, rapid-hardening ('ferro-crete'), 370 lbs. to each wetted and mixed cubic yard of concrete; surface layer, 1½ in. dolerite containing sufficient ¼-in. to ⅜-in. chippings to reduce the voids to 30 per cent. by volume; of this 3 parts; sand 1 to 1½ parts; rapid-hardening cement, 550 lbs. per cubic yard. This cost 9*s.* 8½*d.* per square yard for carriage way 20 ft. wide. Cost, including excavation and surface treatment with bitumen, 9,086*l.* per mile.

Concrete Road Crust.—Southwark; lower course, contains 18 per cent. of stone ¾-in. to 2-in. gauge; upper course, 3 of crushed gravel to 1 of cement; the gravel, 8 of ⅜ in. to ¼ in., 17 of ¼ in. to ¼ in., 75 of ¼ in. to dust, per cent. Such a crust, on roads with 22,000 tons of traffic per week, is treated with silicate of soda, with good results.

Silicated Road Crust.—French practice (Jacques-Thomas): aggregate, hard or semi-hard Jurassic limestone or similar porous limestone; gauge, passing a ring of 1½ in. to 2 in. diam.; coarse sand (the finer kinds, having a tendency to form pasty mortars, are to be avoided). About 40 litres of silicate and ½ cub. m. of sand to each cub. m. of broken stone; say, 6¾ gals., ½ cub. yd., 1 cub. yd. Maximum, of silicate per cub. m., 55 litres, say 9½ gals. per cub. yd. Proportion of silica to soda in the solution, 3·0 to 3·5, the lower figure for porous materials (see p. 734).

Bitumen.—For use in road construction (suggested specification 'Modern Road Construction,' Francis Wood). The bitumen should not contain more than 15 per cent. of fixed carbon. The portion insoluble in carbon disulphide at air temperature shall wholly consist of mineral matter and not more than 4 per cent. carbonaceous matter. Not less than 60 per cent. nor more than 75 per cent. shall be soluble in 88° naphtha at air temperature. It shall be soluble in carbon tetrachloride to the extent of not less than 1½ per cent. less or 1½ per cent. more than the solubility in carbon disulphide. It shall not contain more than 2½ per cent. of paraffin scale.

Nature of Pavings used in London.

Based on the Metropolitan Paving Committee's Annual Reports up to and including the 22nd Report, 1929. The streets, except in the City of London, are classed as First Class, Second Class, and other streets.

The London area offers a favourable field in the study of street pavements. The climate does not approximate to any of the extremes of the British Isles, the gradients are variable, but seldom very steep, and the market for materials is a good one. The traffic conditions which have to be faced include heavy dock traffic, very busy city traffic, that of residential roads, motor omnibus routes, and the great main roads leading to the country. Lastly, the reports of the Metropolitan Paving Committee provide the materials from which deductions can be made as to the value and importance of different pavements, and including comparisons as to wearing qualities and costs.

Percentage Mileages of Different Pavings, 1927–1929.

Table VI. has been prepared on the basis of a table given in the Committee's Twenty-Second Annual Report, 1929, from which the percentages have been calculated.

Cost of Maintenance.—Found by dividing the sum of annual cost of maintenance and annual loan charges for repairing carriageways, by the mileage. Where no entry is found under annual charges, the cost of maintenance is divided by the mileage.

There is no entry under loan charges for the City of London, Fulham, St. Pancras, Southwark, or Woolwich.

The entry for Holborn is 'nil.'

Lewisham.—The cost per mile is calculated from the figure obtained by deducting 21,277*l.*, income, from 89,412*l.*, total expenditure including loan charges. The cost per mile without that deduction is 636·4*l.*

Creosoted Softwood.—Creosoted softwood, chiefly deal and fir, is largely employed, especially for main thoroughfares, and continues to prove satisfactory. In the earlier work a 6-in. 'foundation' of Portland cement concrete was usually provided, but this thickness is not now found sufficient for heavy traffic. Concrete 8 ins. thick is sometimes put down, but for heavy traffic it is usually from 9 to 12 ins. The thickness of the wood-paving is usually 5 ins., but often 4 ins. The blocks are often grouted with pitch, or dipped in a mixture of tar and pitch when they are being laid, but the most usual recent practice is to run the joints with a mixture of hot pitch and creosote oil. The following sizes of blocks are used: length, width, depth; $9 \times 3 \times 5$, $9 \times 3 \times 4$, $8 \times 3 \times 5$, $8 \times 3 \times 4$.

This is now the principal paving for First Class streets; occasionally used in Second Class and other streets.

Life of Softwood Paving.—Edgware Road, 11 years, to 1905; Cannon Street, 16 years, 1906–22; Ludgate Hill, 17 to 20 years; Queen Victoria Street, 17 years, 1908–25; Edgware Road, 17 years, 1905–22; Fleet Street, 19 years, 1903–22; many streets over 20 years (O. E. Winter); Haverstock Hill, paved 1901, 26 years, so far (O. E. Winter).

Strength Crusts for Softwood Paving.—Softwood paving demands a better strength crust to support it than do some other carpetings, and it repays in a greater degree than those the care and money expended in providing the desired strength and the greatest possible trueness of surface. Floating is, however, not desirable, the smaller roughness of the solid concrete being unimportant if the surface is and remains true. For really heavy traffic, double reinforcement is necessary, since single reinforcement, unless at half-depth, only adds to the strength here and there where the conditions happen to suit the disposition. In London, some of the single reinforcement or plain concrete strength crusts recently provided for softwood paving are not good enough to do justice to the qualities of the wood.

Hardwood.—Hardwood pavings have proved very lasting, but are nearly superseded by softwood or other pavings. *Jarrah* has lasted 10 years in the Euston Road, very heavy traffic; 19 years in the Streatham High Road; 10 to 14 years in heavy traffic thoroughfares in Hampstead; 26 years in a first-class street in Hackney; and in other streets 13 to 17 years, and 19 years. *Karri* has lasted up to 21 years. These woods are inferior to softwoods as regards even wearing, and do not so readily take up the armouring of grit which so greatly aids in preventing slipperiness of softwood pavings. In 1915, *sectional Jarrah* blocks, which seem to be better than ordinary blocks of hardwood, were laid in pitch, on a 9-in. concrete 'foundation,' and in some cases re-cut *Jarrah* blocks were re-laid. Since then these woods have been hardly at all used, but some re-cutting and relaying is still carried out.

Wood-paving is now often laid on a thin layer of asphaltic or bituminous material, between the wood blocks and the concrete, but many road surveyors prefer to lay them directly on the concrete.

Asphalt.—Compressed asphalt on a concrete strength crust or 'foundation' is one of the most important heavy traffic pavings in London. The thickness of concrete required varies as in the case of wood-paving, and is practically the same for similar traffic. The thickness of the asphalt carpet is usually 2 ins. or 1½ ins. Compressed rock asphalt is sometimes used for 'other' streets, being a very sanitary paving.

TABLE VI.—LONDON CITIES AND BOROUGHS: PERCENTAGES OF PAVINGS, 1927–1928.

City or Borough.	Total Mileages of Streets.	Percentages of Different Pavings, by Mileages.								Cost of Maintenance per Annum per Mile.
		Wood.	Asphalt.	Granite Setts.	Macadam, Water-Bound, etc.	Tar Macadam.	Concrete Paving.	Bituminous— -grout.	Bituminous— -macadam.

City of London	48·5	(199)	(225)	(49·4)	(—)	(2·32) thousands sq. yd., also, rubber (0·76) and mastic on granite (2·4).				783·3

Asphaltic macadam and asphaltic clinker macadam are used in 'other' streets, and sometimes, especially the latter, in Second Class streets.

Bituminous layers.—Bituminous materials have been employed, in some cases, as carpeting layers only, but in other cases in crusts of sufficient thickness to take a share in distributing the loads. In 1915, only materials of this kind were used for street surface renewals in *Fulham*, usually 2½ to 3½ ins. of 'bituminous macadam' on a 12-in. foundation of hardcore, the surface being treated with liquid bitumen and granite chips or with a 1-in. carpet of asphalt. This construction is very interesting, as it embodies (*a*) a wearing crust which partially distributes the load; (*b*) a foundation which is also a strength crust; (*c*) a wide spread on the road bed and low stresses in this crust, these results being obtained by the use of a considerable depth of relatively cheap material; and (*d*) the initial spread of the load by the wearing crust. In *Hampstead*, 'asphaltic macadam' 1½ ins. and 2 ins. thick was laid, and in *St. Marylebone*, 'bituminous pavements' 1½ ins. to 3½ ins., some of these on old macadam crusts. 'Asphaltic graded granite' 3 ins. thick was put down in *St. Pancras*, and 'asphalt macadam,' 4 ins. deep in two layers on existing macadam, in *Woolwich*.

Bituminous crusts and carpets are now largely employed for 'other' streets, destructor clinker being sometimes used as the aggregate.

Tar macadam.—The following were laid in 1915. Tar macadam (granite) 3 ins. thick on old macadam: tar macadam 4½ ins. thick: tarred slag macadam, 4 ins. thick on a foundation of hardcore, and 4½ ins. thick on 'an old foundation.' Since then the use of this form of paving has extended. Work noted in the 1925 report includes: 4-in. 2-coat work on hardcore foundation; seven roads of the 'other' street class in Hammersmith, 4 ins. tar-slag macadam; 3½ ins. tarred limestone macadam on existing macadam; and 4 ins. tar-slag macadam, replacing granite sett paving.

The 1926 report describes work with tar-slag macadam and tarred limestone macadam.

Stone paving.—Considerable areas were paved, in 1915, with small granite setts, the usual depth being 4 ins.; also, Aberdeen granite setts, 4 × 6 ins. on a 12-in. crust of cement and clinker concrete. Re-dressed Aberdeen granite setts 3 ins. by 6 ins. were laid on 6 ins. of concrete; fine dressed 'Norwegian' granite setts were laid in cement and sand grout on 12 ins. of concrete; and setts, 4-in. cubes, laid in 1 in. of ashes and grouted with pitch grout, on a macadam crust.

The 1925 report gives particulars of the use of setts in Deptford; in Tunnel Avenue, Greenwich, traffic 75–100 tons per yard width per hour; in Lambeth, a First Class street, and an 'other' street; in Whitefriars Street; in Poplar; and in Stepney, several streets. The part played by stone setts, now no longer used for main thoroughfares as such, is indicated by the nature of the traffic in the localities mentioned.

The 1926 report refers to stone sett paving in Stepney, St. Pancras, and Greenwich.

The trend of practice, as shown by the later reports, may be studied under 'Replacements,' p. 746.

See also p. 737, 'Chelsea Embankment.'

Filler for Concrete Pavements.

A cement-coloured filler for filling cracks and joints in concrete pavements, which does not give the unsightly appearance of the black lines resulting from the use of the bituminous fillers commonly employed consists of approximately twelve parts rosin, one part crude rubber, with sufficient barium sulphate to give the desired colour. In preparation the rubber is dissolved in petrol, and the rosin is then mixed in with an application of heat, the colouring material being added as required. Any desired consistency can be obtained by varying the proportions. A material with remarkable adhesive properties is produced, and it can be heated so that it will flow into the cracks and joints.

Recent Practice and Costs of Pavings in London.

Foundations.—Recent foundation work includes 11 ins. 6 to 1 concrete with 'fabric' reinforcement; 8 ins. 'Ciment Fondu' 6 to 1 concrete with 'fabric' reinforcement; 9 ins. 6 to 1 concrete, similarly reinforced, several cases; 12 ins. concrete; 12 ins. clinker concrete; 9 ins. clinker concrete; 6 ins.-clinker concrete ('other' street); 6 ins. concrete, a notable case, as this (Mile End Road) is a First Class street; 4 ins. reinforced concrete ('other' street); 9 ins. reinforced concrete ('other' street); 6 ins. concrete, a notable case, Commercial Road, East. Both the First Class streets noted as having been provided with 6-in. concrete foundations are sett-paved; but as this paving has no crust strength, the difference in thickness of foundation compared with other streets is remarkable.

Rapid hardening cements ('Ferrocrete' and 'Ciment Fondu') have been used, for the whole foundation or for floating, in many cases. Much foundation work in London is without reinforcement. That usually employed is a single layer with different spacings of lengthwise and transverse rods.

APPROXIMATE GRADING ANALYSIS.

Base.		Wearing Surface.

By weight the amount of bitumen would be 9 per cent. and 14 per cent. respectively.

The cost of wood paving in Fulham may be gathered from the fact that the Council allotted 10 years ago the sum of 4,000*l.* per annum to maintain 160,000 sq. yards; this has now been increased to 202,268 sq. yards without increase in allotted sum. Any surplus not spent is placed to a reserve; this reserve at the end of 1916 was 12,000*l.*, sufficient to repave one-seventh of the whole area. The average cost is therefore 5*d.* per sup. yard per annum; the cost of the heaviest trafficked road does not exceed 9*d.* per sup. yard, even allowing for the concrete foundation. It has been stated in the Committee Rooms of the Houses of Parliament that local authorities have roads which cost over 2*s.* and which are of macadam.

The motor bus damages the road to no greater extent than the steam lorry, if as much, as many of these have steel tyres.

(Francis Wood.)

ANNUAL COSTS PER SQUARE YARD.

In the cases of some of the road crusts or pavings which were replaced or renewed, the annual cost of maintenance of the worn-out or superseded crust or paving is given:

Water-bound Macadam, sprayed or unsprayed; 'other' streets, considerable traffic, 6½*d.*, 3½*d.*

Compressed Rock Asphalt.—First-class streets; very considerable traffic, 1*s.* 10*d.*; considerable traffic, 1*s.*; 'other' streets, 8*d.*

Softwoods.—Creosoted deal, Westminster Bridge Road, 8½*d.*; yellow deal, Regent Street, laid 1906, 10½*d.*; softwood, Northumberland Avenue, a very wide street, not heavy traffic, 6*d.*; second-hand, reconditioned blocks, laid 1917, 1*s.* 2½*d.*

Wood.—Presumably hardwood, Aldersgate Street, laid 1874, 1*s.* 0½*d.*

Asphaltic Macadam, laid 1917, Vauxhall Bridge, very heavy traffic, 1*s.* 3*d.*

Granite Setts.—Replaced, 1927, by asphalt, average annual cost of the sett paving, 2*d.* per sq. yd.

REPLACEMENTS AND COSTS: TWENTIETH AND TWENTY-SECOND REPORTS.

(Numbers higher than (24) relate to the Twenty-Second Report.)

Water-bound Macadam: (1) Replaced by bituminous-bound clinker and bituminous carpet, cost, using old materials, 10*s.* 8½*d.*; (2) by 2½-in. bituminous carpet on the regraded surface, cost, 6*s.* 4*d.*; (3) by 4-in. tar-slag macadam, cost, including strengthening of foundations, 8*s.* 8*d.*; (4) by 3½-in. bituminous-grouted macadam, cost, of preparation, 1*s.* 7*d.*, of the paving, 7*s.* 1*d.* (2 years' free maintenance); (5) by 3-in. asphalt macadam, cost, of preparation, 5*s.* 5½*d.*, of the paving, 10*s.* 6*d.* (5 years' free maintenance); (6) by 4-in. tar-slag macadam, cost, of preparation, 1*s.* 11*d.*, of the paving, 8*s.* 4*d.* (5 years' free maintenance); (7) by bituminous paving, 2¾-in. asphalt concrete, 1½-in. carpet, cost, of preparation, 2*s.* 11½*d.*, of the paving, 14*s.* 3½*d.* (5 years' free maintenance); (8) by 3-in. bituminous macadam, cost, of preparation, 4*s.*, of the paving, 7*s.* 11*d.* (3 years' free maintenance); (9) by 2-coat asphalt macadam, 5-in., cost, of preparation 4*s.* 10*d.*, of the paving, 12*s.* 6*d.* (5 years' free maintenance); (10) by clinker asphalt, 1½-in. base, 1-in. carpet, hardcore foundation regraded, cost, of preparation 4*s.* 2*d.*, of paving, 7*s.* 4*d.*; (11) by creosoted deal on 8-in., 6 to 1, rapid hardening cement concrete, cost, of foundation, 16*s.* 11*d.*, of the paving, 13*s.* 4*d.*; (12) by Trinidad Lake asphalt macadam, cost, of preparation, 1*s.* 4*d.*, of the paving, 7*s.* 6*d.*; (13) by 3-in. granite concrete; 1 'Ferrocrete,' 1 sand, 1 of ⅜-in. granite chippings, 4 of 2-in. granite, surface dressed with silicate of soda, cost, including reshaping the old crust, 11*s.* 3*d.*; a similar case, 17*s.* 6*d.*; (14) by granite setts, 5-in. deep, on 6-in. reinforced concrete, cost, 39*s.*; (25) a number of cases in which the old surface has been prepared, or the old material used, for bituminous surfaces, as (*a*) cold as asphalt ('Carpave') 2-coat work; total cost, 6*s.* per sq. yd.; (*b*) grouting with cold emulsion, preparing old surface 9*d.*, surfacing 9*s.* 6*d.*; (26) by 2 ins. of

compressed asphalt on 9 ins. of Thames ballast concrete; cost of foundation, 14*s.* 6*d.*, of the paving 10*s.* 9*d.*; (27) by destructor clinker asphalt (Fulham), 1-coat work, 2½ ins., on regraded hardcore foundation; cost, 6*s.* 7*d.*; (28) by redressed setts, cement grouted, on 6 ins. of 6 to 1 Thames ballast and rapid hardening cement concrete; cost of foundation and surfacing, 24*s.*

Tar-slag Macadam, (15) replaced by 8-in. concrete with a granolithic surface, cost, 29*s.* 6*d.*; (29) by whinstone treated with bitumen, 4 ins., 2-coat work, on rolled bottom, 9*s.*; (30) by granite rapid hardening cement concrete; cost of foundation and surfacing, 14*s.* 9*d.*

Tar Macadam, (16) replaced by creosoted deal, laid dry and close, grouted with pitch or bitumen; on 12-in. or 9-in. lightly reinforced concrete foundation, cost, of foundation, 14*s.* 5*d.*, of the paving, 10*s.* 4*d.* (2 years' free maintenance); (35) by a surfacing of crushed granite, sand, and bitumen, 2 ins. on 9 ins. concrete foundation, cost of foundation and surfacing 23*s.* per sq. yd., with 5 years' maintenance; (36) by 2½ ins. asphalt, laid hot on existing surface; cost of preparation, 11*d.*, and of the surfacing, 8*s.* 3*d.*

Asphaltic Macadam, (17) replaced by softwood; cost of paving, 13*s.* 3*d.*; (35) by 2-in. compressed asphalt on 9-in. concrete; cost of foundation, 14*s.* 9*d.*, of the paving, 9*s.* 9*d.*

Jarrah, laid 1912, (18) replaced by creosoted softwood; cost of paving, 15*s.* 1*d.*; (19) by creosoted deal on 12-in. clinker concrete foundation, 1-in. floating, cost, of foundation, 21*s.* 5*d.*, of the paving, 12*s.* 1*d.*; (20) a similar case, cost of paving, 9*s.* 6*d.*; Jarrah blocks laid in 1901, by (34) creosoted deal on 12-in. concrete foundation, cost of foundation 23*s.* 2*d.*, of the paving, 15*s.* 6*d.* Another similar case, Jarrah laid in 1922; cost of new work, 34*s.* 2*d.*

Compressed Rock Asphalt, etc., (21) laid 1911, replaced by softwood, cost of the wood paving, 13*s.* 2*d.* (2 years' free maintenance).

Norwegian Granite Setts, (22) laid 1911, replaced by Aberdeen granite setts, 8 ins. by 5 ins. by 4½ ins., fine dressed, cost of the paving, 42*s.*

Granite Setts, (23) replaced by 2 ins. compressed rock asphalt on 9-in. concrete, cost of foundation 14*s.* 11*d.*, of the paving 17*s.* 10*d.* (5 years' free maintenance); (31) by mastic rock asphalt, 2 ins., made with granite chippings on 6 to 1 Thames ballast and rapid hardening cement concrete, cost of foundation 9*s.* 8*d.*, of the paving, including 2 years' maintenance, 10*s.*; (32) by pitch grouted creosoted deal, on 9 ins. of 6 to 1 Thames ballast and rapid hardening cement concrete, cost of foundation 25*s.* 6*d.*, of the paving 11*s.* 3*d.*; (37) by compressed asphalt on 6-in. concrete, cost 21*s.* 2*d.*, with 5 years' maintenance.

Creosoted Deal, laid 1914, replaced by (24) Swedish granite setts, bitumen-grouted, cost of the paving, 33*s.* 8*d.*; (33) by clinker asphalt, 3½-in. base and 1½-in. topping, rolled hot (Fulham), cost of foundation and surfacing, 12*s.* 6*d.*

Experimental Rubber Paving.

Various types of rubber paving have recently been put into service, on trial. In *Southwark* (Mr. A. Harrison) two kinds have been put down: (*a*) slabs, 9 ins. by 3 ins. by ½ in., vulcanised on expanded metal and anchored to concrete: (*b*) composite blocks, 8 ins. by 4 ins. by 4 ins., laid on a concrete foundation, like wood blocks. The second type is regarded as likely to prove successful.

In *Glasgow* and *Edinburgh* (1923) a different method has been adopted (described by Mr. E. J. Edwards). The rubber block, 9 ins. by 4½ ins. by 2 ins., is fixed by means of an embedded steel spike into a concrete base of slightly smaller dimensions. These blocks were laid on a concrete foundation, and were grouted in with pitch or cement. It is thought desirable to lay this paving when the concrete foundation is still green; if not, the blocks should be laid with bitumen and grouted in with pitch and bitumen. The top layer of the blocks laid in Edinburgh and Glasgow contained 30 per cent. of plantation rubber. The present cost (Mr. E. F. Spurrell) of a rubber paving includes about 4*l.* per sq. yd. for the rubber alone.

Matters demanding attention are: the question whether green concrete will set properly under the impervious paving; whether oil spilt on the roadway will seriously harm the rubber; and whether rubber paving can be effectively restored after excavation.

A rubber *footway* laid down in Edinburgh twenty years ago has been found to have lost only a fraction of an inch of its thickness.

London, 1926.—An experiment is being tried in New Bridge Street, Blackfriars, where rubber as a road surface is to be subjected to a very severe test.

Heavy terra-cotta blocks (known as 'Gaisman' blocks), 10⅛ ins. by 8 ins., are laid as a base to hold a superimposed rubber cap, ⅝ in. in thickness. This is put on by a process which, it is claimed,

will withstand the pounding and spreading force of the heaviest traffic. The blocks with these rubber caps are laid on a 12-in. concrete bed, with a cushion of sand ⅜ in. thick. They are set in by means of joints, composed of a special bitumen and rubber mixture. During 1927 this paving showed no sign of wear until about November, when flaking off of considerable fragments of the rubber was seen to be taking place here and there, probably due to the sudden 'braking' of vehicles on dry days, and the pressure of grit. It is possible, however, that the blocks which have suffered may have been defective. It is more slippery than the adjacent wood paving, but less slippery probably, than asphalt. Greasiness in wet weather is partly due to pulverized gritting material brought on to it from adjacent wood paving.

By the end of 1928 the blocks adjacent to grids, manholes, and, in some places, alongside the strip of other material separating them from the kerb, had suffered considerably. The fairer test, the condition of the blocks in the remainder of the area, was inconclusive, the wear not being sufficient to indicate approaching failure, nor so little as to suggest successful competition with other pavings as regards cost. Except for some further wear, and evidence of tendency, in a proportion of the blocks, to surface peeling, these remarks apply to the condition of the paving at the end of 1929.

Bradford, 1927.—A small area of experimental paving consisting of wooden blocks, in each of which there is a number of metal caps, each containing a rubber 'egg.' The cups and 'eggs' are replaceable. (Inventor, P. Henry.)

London, 1928.—Laid in January (*J. S. Cowper*), in Thurloe Place, close to South Kensington Station. A 2½-in. carpeting of 'Cowper' blocks on a concrete strength crust, single reinforcement. Each block, in plan, two 9-in. × 4½-in. areas joined by half-length overlap. No fixing devices; middle third provides tongue and groove joint ½-in. deep; lugs and slots in ends of bottom third; made to the camber; tapped into place; no jointing material; surface finely striated to give initial rugosity. Top layer 'durable rubber,' shock absorbing; bottom layer soft enough to sit tightly on the concrete; middle layer harder material, with a high coefficient of elasticity. After 9 months, in perfect condition, the fine striations being hardly dimmed. Condition very good at the end of 1929.

Glasgow.—A street crossing, 40 ft. × 10 ft.; experimental. Paved May 1923 with blocks 9 in. × 4½ in. × 4 in. deep (2½ins. of rubber fixed with steel binders to a 2-in. block of concrete); supplied by North British Rubber Company. Cost of blocks, 5*l*. 11*s*. 7*d*. per sq. yd.; cost of laying, about 10*s*. per sq. yd. In November 1928, no appreciable sign of wear, good condition very heavy vehicular traffic.

Edinburgh.—The same paving, also laid in 1924, was, in 1929, reported by the city engineer to have given every satisfaction and to be in appearance as good as when laid; medium traffic.

London, Fresh Wharf.—400 sq. yds. on a gradient of about 1 in 24. T-irons are embedded in the concrete foundation, from kerb to kerb at intervals of 12 to 15 ft., to prevent creep of the blocks. These are 8 ins. by 4 ins. by 3 ins. deep, with vertical sides. The lower 2½ ins. is of hard rubber, on which a ½-in. cap. of soft rubber is mounted. The blocks were dipped in hot bitumen when being laid. Supplied by the Leyland and Birmingham Rubber Company. Considerable traffic, mainly heavily laden vans and lorries. Reported as not creeping and showing very little sign of wear in 1929.

Effects of Motor-Omnibus Traffic and other Heavy Traffic.

Some years before the war reports of the Paving Committee showed that heavy motor traffic had increased the cost of maintenance of macadam roads generally. As regards paved streets and roads, the cost of maintenance had increased in those areas in which the stage of strengthening and improvement had been reached, but had increased only slightly or not at all where this stage had been passed. When the cost of reconstruction had been taken into account on the one hand, and actual increases in the passenger-mileage and ton-mileage on the other, it seemed that the economics of road maintenance in London had not been changed for the worse, though the cost of cutting through the greater thickness of concrete provided a new argument in favour of the scheme for providing subways for the various conduits under the main streets.

Surfaces for Steep Gradients.

Bituminous-bound Destructor Clinker.—Muswell Hill 1 in 10; varied traffic, including London omnibuses.

Broken-stone, Cement Grouted.—Rapid hardening cement; used for gradients of 1 in 15 and 1 in 10.

Tar-Macadam.—Aberdulais-Resolven Road, 1 in 11. In Blackburn (A. T. Grosseman) gradients up to 1 in 6.

Asphaltic-Slag Macadam.—Gradients up to 1 in 12.

Tests of Road Stones.

(See Report to the Third International Road Congress, T. E. Stanton and R. G. Batson.)

The equipment of the National Physical Laboratory, Teddington, enables the following test of road stones to be made :—

(1) A dry attrition test (resistance to wear); (2) a wet attrition test; (3) an abrasion test (for hardness); (4) a repeated impact test (toughness); (5) a test of the cementation value: (6) an absorption test.

Attrition test.—The machine is of the 4-cylinder Deval type, as used in France and in the United States. The cylinders are $7\frac{1}{2}$ ins. in diameter and 14 ins. long, set at 30° to the axis of rotation. About fifty pieces of the rock, weighing eleven pounds, are placed in one of the cylinders, and the machine revolved 10,000 times at about 30 revolutions per minute. Only the material which will pass a sieve of $\frac{1}{16}$ mesh is counted in measuring the amount of wear, which is recorded both as a percentage and by the French coefficient $\frac{40}{\text{percentage of wear}}$.

In the wet test 1·1 gallon of water is used with 11 lbs. of stone. The wear is usually greater in the wet than it is in the dry test; but not always.

Repeated impact test.—This test is made with the Page impact machine, which has a hammer weighing 4·4 lbs., delivering the blows through a plunger, the surface of which, in contact with the specimen, is spherical to a radius of 0·4 inch. The test piece is a cylinder, 1 in. by 1 in., ground to the true diameter, and cut to length by a diamond saw. The test consists of a series of blows, beginning with a fall of 0·4 inch, which is increased by 0·4 inch with every successive blow until the test piece is broken. The toughness is measured by the number of blows. Tests can also be made with a constant height of fall.

Abrasion test.—The test piece is prepared in the same way as for the impact test and is of the same size. The machine is of the Dorry type, and consists of a cast steel disc revolving in a horizontal plane. The test piece is held, with its axis vertical and with a load equal to 3·5 lbs. per square inch, against the surface of the disc 26 cms. from the centre. Standard sand of 30 to 40 mesh is fed continuously through funnels at a definite rate, the same in each case. After about 1,000 revolutions of the disc, at the rate of 28 per minute, the test piece is weighed and the loss of weight noted. The test is repeated on the other end of the test piece, and the average loss of weight by the two runs is recorded. The hardness is measured by $(20 - \frac{1}{3}W)$ where W is the loss of weight in grammes per 1,000 revolutions.

Cementation test.—Coarsely crushed rock, weighing 1·1 lb., is ground in a ball mill with 0·02 gallon of water, the balls being steel shots (two) 5·1 ins. in diameter. The material is ground for two and a half hours at the rate of about 2,000 revolutions per hour. The resulting paste is moulded into briquettes, 1 in. diameter and 1 in. long, the maximum pressure being 1,880 lbs. per square inch. After twenty-four hours, the briquette is dried for twenty hours in the air, and for four hours in a hot air bath at 200°F., cooled for twenty minutes in a dessicator, and then tested. It is placed on the anvil of the machine, with its axis vertical, and struck through a plunger by a small hammer with an effective drop of 0·4 in., the rebound being measured by the movement of a lever attached to the hammer, and holding a pencil against a paper-covered revolving drum. This records the number of blows required to destroy the resiliency of the test-piece, after which there is no rebound. The mean of six tests is taken as giving the cementing value of the material.

Crushing strength.—The specimen is a cylinder 1 in. in diameter by 1 in. long, ground out of a rough sample by emery-wheels. The cracking stress and crushing stress are measured.

Specific gravity.—Three samples are taken from each batch of stones, and the average specific gravity recorded as that of the batch.

Absorption of water.—A stone of about 13 lbs. is weighed in air and then in water. It is kept in water for three days and is then weighed in air. If A=weight in air, B=weight in water immediately after immersion, and C=weight in water after immersion for three days, the number of pounds of water absorbed per cubic foot of rock is nearly

$$\frac{C - B}{A - B} \times 62{\cdot}5.$$

Petrological analysis.—The classification of the rock, in the terms of geological nomenclature and as regards its constituents, is made in the Geological Museum, London, S.W.

Samples.—The minimum number of stones sent in the case of a rock to be used as a road stone, if suitable, should be 250, broken to the shapes and sizes usual in road work. For the abrasion and impact tests eight stones should be sent, about $1\frac{1}{2}$ ins. by $1\frac{1}{2}$ ins. by 3 ins. Samples should be sent in strong wooden boxes or in separate compartments of cases. The position of the quarry must be so described that its locality can be identified by the Geological Survey map; or a piece of the map with the position marked on it may be sent.

TESTS OF BITUMINOUS MATERIALS.

Penetration Test.—The material to be tested is usually brought to a definite temperature, which for standard comparisons is 77° F. (25° C.). The penetrometer consists essentially of a weighted needle attached to the 'hand' of a dial by a simple mechanism so that the hand on the dial registers the distance moved by the needle. The point of the needle is brought to the surface of the specimen, the dial reading noted, the needle released for one second or sometimes longer, and then held. The difference between the two readings on the dial measures the penetration. It is desirable to make tests with different weights on the needle and at different temperatures.

Viscosity Tests.—Materials too soft for the needle penetration test may be tested by several methods, including the following: The *Crosby Consistometer* consists of a balanced wheel, grooved at the circumference and provided with a device to measure the arc through which it turns. Wheels of 4 ins. and 8 ins. diameter have been used. At one end of a thread which passes round the circumference of the wheel is a small hook, to which plungers can be attached, and at the other end is suspended a pan for weights. An excess load of 0·3 gramme is required to overcome friction and inertia. The machine measures the distance moved through by a disc of known area under a known load, through a substance contained in a box of fixed dimensions, during five seconds. The plungers are round brass discs with spindles in the centre. The box is 2½ ins. in diameter and 1 in. deep for ordinary materials, 5 ins. deep for very fluid materials. The plunger is immersed, the weight placed in the pan, partly counterbalancing the weight of the plunger and leaving a known downward force which is left to act for 5 seconds, and moves the plunger through the material under test for a distance which can be accurately read on the measuring device. The *float apparatus* of the New York Testing Laboratory measures the time taken before a plug of the substance under test becomes warm enough to flow under given conditions. The plug of the substance is in a brass collar attached to a float or saucer which is floating in water. The temperature of the water is maintained constant, at 90° F., for instance, until the plug is sufficiently soft to allow the water to enter the saucer and sink it. The temperature of the plug at the beginning of the test is fixed by keeping it for 15 minutes in cold water at a constant temperature.

Solubility Test.—Solubility in carbon disulphide. A small quantity is placed in a weighted flask containing 100 c.c. of carbon disulphide, and afterwards decanted through an asbestos mat and the precipitate dried and weighed.

Other Tests.—Appropriate methods are employed for determining the specific gravity, the melting point, and the coefficient of expansion.

ROAD CRUST WORK AND STREET PAVING.

Quarrying.—Ayrshire, quarrying road metal, 3*s.* 2*d.* per ton; quarrying and tarring, 9*s.* 4*d.* per ton. Herefordshire, 13*s.* 3*d.* per ton, including depreciation of plant.

Power Cost Data (E. Dalton).—Quarrying: oil-engine compressor, drills, etc., 100 h.p.; fuel oil nearly 0·4*d.* per brake horse-power-hour; average load factor, 50 per cent.; fuel oil and lubricating oil, 0·75*d.* per ton of rock quarried, the calorific value of the fuel oil being 19,400 B.Th.U., and lubricating oil 3*s.* 6*d.* per gallon.

Stone-breaking Plant.—Output 70 to 80 tons of road metal per day; cost about 2,000*l.*

Road Metal.—Warwickshire, granite and basalt, 23*s.* 8*d.* per ton; West Riding, granite, 17*s.*; Lichfield, gravel crushed at the pit, 7*s.* 10*d.* per cub. yd., or 6*s.* 8*d.* per ton; other cases, 19*s.* to 23*s.* per ton. Truro, roadstone, 4*s.* 10*d.* per ton. Somerset, limestone, 4*s.* 6*d.* per ton on lorry at quarries; tar-macadam, 14*s.* 8*d.*

Quantities used in a Year.—680 miles of road, 216,000 tons, including 64,000 tons of tar-macadam; 284 miles of main road, 38,000 tons; 634 miles of road, 132,000 tons, including 32,000 tons of granite coated with tar and bitumen. Per mile, in a year, crust renewals, 269 tons to 360 tons.

About 610 miles; nearly 44,000 tons of granite chippings treated with tar and bitumen in the county hot mixing plants. About 1,400 miles, nearly 944,000 galls. of tar and 259,000 galls. of bitumen used for treating about 6½ million sq. yds. of road surface. 812 miles, 255,000 tons of road materials, 959,000 galls. of tar and other surface dressings; 550 miles, 16,000 tons of tarred slag, 5,400 tons of tarred limestone, 203 tons of tarred granite.

On 662 miles of county roads; 94,700 sq. yds. of bituminous coatings, 20,305 tons of tarred macadam (slag 14,689, limestone 3,660, granite 1,956), 3,529 tons of limestone and granite chippings used in semi-grouting work. For about 218 miles of roads, 47,000 tons of materials purchased.

On 513 miles of county roads; 19,268 tons of Clee Hill stone; 16,161 tons of limestone; 878 tons of slag; 11,967 tons of tarred macadam; 566,247 gal. of bitumen and tar.

Consolidating Road Metal.—Several counties, about 1*s.* 10*d.* per ton ; also 2*s.* to 2*s.* 3*d.* ; lowest figure noted, 1*s.* 1½*d.*, 1925. Staffordshire, 1927, carting materials and forming the road crust, 29*s.* 10*d.* per ton, or 3*s.* 9*d.* per sq. yd. ; consolidated thickness, 4 ins., 1929. Northamptonshire, 1929, 11·65*d.* ; Holland, Lincolnshire, 8·83*d.*

Tar-Macadam Plant.—Durham County Council, output 1,000 tons of tar-macadam and 1,000 tons of all-grade dry slag per week.

Tar-Macadam Crusts.—Various counties : 4-in., about 7*s.* 3*d.*, using old stone, about 6*s.* 2*d.* per sq. yd. ; per ton, 36*s.* ; Midlothian, 3*s.* 7*d.* per sq. yd. Dorking : analysis of making up roads with tar macadam, including deep scarifying and strengthening of haunches (S. S. Gettings)—Main roads : materials, 73·2 per cent. ; manual labour, 9·2 per cent. ; team labour, 6·3 per cent. ; scarifying and rolling, 10·1 per cent. ; tradesmen's bills, 1·2 per cent. 'Assisted' roads : materials, 66·6 per cent. ; manual labour, 9·7 per cent. ; team labour, 13 per cent. ; scarifying and rolling, 8 per cent. ; tradesmen's bills, 2·7 per cent. Herefordshire : tarred material, 3-in. coatings, mixed hot with tar, squeegeed with bitumen, 6*s.* per sq. yd., or, if tarred chips are used instead of the bitumen, 5*s.* 6*d.* per sq. yd. London : 3½-in. tarred limestone, 7*s.* 1*d.* Sunderland : tar macadam, 4 ins. thick on 10-in. punning, 8*s.* 9*d.* per sq. yd. Another case, a 4-in. crust, 8*s.* 6*d.*, or with 12 ins. of hardcore base, 14*s.* 6*d.* per sq. yd. Morecombe Ring Road : tar-macadam top course (see 'New Roads'). London (Wandsworth) : trial stretch of tar macadam ; traffic 24,000 tons per day. Tar-macadam metal, per ton, 36*s.* Watford By-pass road, 17,500 sq. yds., at 7*s.* 6*d.* Newport, Mon. : 200 tons used. Tar-slag, per ton, 22*s.* 6*d.* ; dry slag, 12*s.* 6*d.* Somerset : main roads, 1929, 2½-in., 4*s.* 2*d.*

Reinforced Tar-Macadam.—A road near Hull (T. W. Chapman) : traffic, 4,000 tons per day and upwards ; reinforced tar-macadam crust had been practically untouched after three years' service. Leeds : reinforced tar-slag macadam. Warwickshire : experimental, reinforced tarred slag, 6 in. by 6 in. mesh, 6*s.* 3*d.* per sq. yd.

Tar-Macadam.—Recent data ; Ossett, laid on 10 ins. of local stone pitching ; Sidmouth, most of the local roads are of tar-slag macadam ; Swaffham, Urban District : usual practice, re-surfacing with tarred materials with concrete margins for horse traffic. Swindon, tar macadam replacing water-bound crusts.

Totnes : 2 in. to ½ in. stone, one coat, 3 ins. thick ; covered with granite chippings before rolling ; surface sealed with cold emulsion and ⅜-in. granite chippings ; cost, 3*s.* 2*d.* to 3*s.* 7*d.* per sq. yd.

Semi-grouted Crust.—Isle of Wight ; using crushed limestone, 2 ins. to ¾ in., produced at 5*s.* 6*d.* per sq. yd. ; crust formed by wet rolling ; bitumen emulsion applied, 1 gal. per sq. yd. Surfaced with ¼-in. chippings, 140 sq. yds. per cu. yd. ; rolled ; sealed, ½ gal. per sq. yd. ; blended with ¼-in. chippings ; cost about 3*s.* 4*d.* per sq. yd.

Grouted Limestone.—Chard ; main road programme, 1928, 24,000 sq. yds. of grouted limestone 1½ in. thick.

Tar-bitumen Grouting.—Hot application ; crust 5 ins. before rolling ; from 2½ gal. to 1 gal., usually 1¼ gal., per sq. yd. ; cost about 3*s.* 3*d.*, or from 1*s.* to 1*s.* 6*d.* more than the costs of the same crusts waterbound.

Bituminous Tarmacadam.—Sandstone, or gritstone, broken 2 ins. to ¾ in. ; 10 gal. of 60 per cent. bitumen and 40 per cent. tar mixture ; 3-in. crust ; sprayed and gritted ; contract price, 4*s.* 7*d.* per sq. yd. ; tarred every year. Roads so made up cost 260*l.* per annum for maintenance. Similar crusts cost 5*s.* 8d., 4*s.* 8*d.*, 6*s.* 4½*d.* per sq. yd.

Tar-slag Macadam.—Recent data ; five roads leading to Queensferry Bridge, surfaced with tar-slag macadam ; Norfolk, 73 miles of roads converted to tarred slag in one year ; Warwickshire, main road reconstruction, 3-in. to 5-in. tarred slag, 2-coat and 3-coat, on slag foundation.

Bristol-Avonmouth road, between Bristol and Shirehampton, nearly all tarmac. Norfolk, 1923, 17½ miles of tar-slag (see 'New Roads' and 'London'). Laying 3-in. of tar-slag macadam on a prepared foundation, about 5*s.* per sq. yd. Strengthening a water-bound crust and surfacing with tar-slag, 5*s.* 4*d.* per sq. yd. London, 2-in. bottom course, 1½-in. second course, ¾-in. to ½-in. topping, 7*s.* 2*d.* per sq. yd. ; 4-in., 8*s.* 8*d.* per sq. yd., with 3 years' maintenance ; Hampshire : county main roads, 1925-1926, tarred slag used, 15,000 tons.

Tarmacadam Footpaths.—Market Harborough : reconstruction ; new materials, tar, ashes for bedding, and slag dust for top-dressing. A portable 'cracker' used for breaking up the old material. Ten gal. of tar mixed with 7 barrows of the broken material, by hand ; rolled with an 8-cwt. roller. Cost per sq. yd. : labour, 6*d.* ; haulage, 1½*d.* ; tar, at 7½*d.* per gal., 5¼*d.* ; slag dust, ¼*d.* ; petrol and oil, ⅛*d.* ; surface tarring, 3½*d.* Total, 1*s.* 4½*d.*

Asphalt.—Hendon, main roads, 2-in. carpet on reinforced concrete; Northants., main roads, 2-in. carpets; Wrexham, main streets, 2-in. carpets on reinforced concrete. Asphalt carpets laid in 1927 included stretches of roads in Essex, Lincolnshire, Warwickshire, Hertfordshire, and Dumbartonshire, and on the Great North Road.

Synthetic Asphalt Plant.—Outputs of three sizes, tons per hour, 4 to 6, 8 to 10, 12 to 15; corresponding to square yards of carpet 2 ins. thick per ten-hour day, 400 to 600, 800 to 1,000, 1,200 to 1,500.

Asphalt Macadam.—Trinidad asphalt macadam, 2-coat work, 3-in. and 1½-in., 15*s.* 6*d.* per sq. yd.; 4-in. 13*s.*, with two years' maintenance. Warwickshire, 2-coat, 2-in. and 1-in.

Asphaltic Macadam.—Two-coat; 2 ins. and 1 in.; 11*s.* per sq. yd.; no appreciable wear in 3 years; deepest depression, ⅜ in.; usual 'wave depth,' ⅛ in. to ¼ in.

One-coat asphaltic (Trinidad) macadam: 2¾ in.; stone graded, 1¼ in. to ¼ in.; 10 per cent. cement filler; 10 per cent. bitumen; 25 per cent. sand; cost, 10*s.* per sq. yd.; 'no appreciable' deterioration after 3 years.

Asphalt Carpet.—On concrete strength crust; Northern Ireland: 17*s.* 10*d.* per sq. yd., with 10 years free maintenance. Also, 2-coat asphalt 9*s.* 6*d.* per sq. yd., 5 years free maintenance.

Clinker Asphalt.—London, 2½-in., 7*s.* 10*d.*, with five years' maintenance; 6,000 tons, most clinker asphalt, laid in Huddersfield, 1925, 7*s.* 4*d.* per sq. yd. Cheltenham, clinker asphalt for the roads is made at the destructor works; York, 2-in. clinker asphalt on 6-in. reinforced concrete foundation; Sheffield, about 800,000 sq. yds. of streets, clinker asphalt.

Clinker Asphalt Plant.—Huddersfield, 45 tons per eight-hour day.

Bituminous Macadam.—County Londonderry: 4 ins. of coreing, blinded with gravel and consolidated; 4-in. coat of hot bituminous macadam, graded 2 ins. to ¾ in.; rolled; sealed with Road Board tar mixed with 30 per cent. of bitumen; gritted with ¾ in. to ¼ in. whinstone chippings; rolled. Also, on good waterbound macadam crusts, 2-in. carpet of hot-laid bituminous macadam.

'Bituminous' Work.—London, 2-in. carpet, stone-filled; bituminous paving, 5-in. 12*s.* 1*d.*, with one year's maintenance; bituminous grouted macadam, 3½-in., 11*s.* 7*d.*, 2 years' maintenance; 2-in. carpet, 7*s.* 11*d.*, with five years' maintenance; 4-in. paving, 11*s.* 8*d.*, with five years' maintenance; 2-in. carpet, aggregate of graded granite, 8*s.* 6*d.* per sq. yd., with five years maintenance. Blackpool, 2-coat surfacing, 9*s.* 6*d.* per sq. yd. 'Bituminous asphalt,' 2-in. 3*s.* 3*d.* to 3*s.* 10*d.*; and 3-in., 5*s.* 7*d.*; 3½-in., 6*s.* 1½*d.* per sq. yd. Hampshire, 2½-in. carpet 7*s.* 8*d.* per sq. yd., 1 ton covering 7·3 sq. yds.

Black-base.—Largely used in the Western States, U.S.A. A generic term for lower courses or strength crusts with stone, slag, or gravel aggregate and 4 to 6 per cent. of bitumen, usually mixed hot. Five states have 2,500 miles of such lower courses.

Water-bound Crusts.—Herefordshire, good limestone crusts for light and medium traffic, tar-sprayed twice, spread with chips, 3*s.* per sq. yd. (not including foundation work). Cornwall, water-bound surfacing, 1*s.* 11*d.* per sq. yd.; Basingstoke, reforming old crust and adjusting camber, 2*s.* 6*d.* per sq. yd. Durban, resurfacing with macadam, 5*s.* 1*d.*

Strength Crusts.—Durban, 9*s.* 10*d.* per sq. yd.; 14-in. of large stone pitching, hand-packed, filled with spalls; on this 2-in. of whinstone, rolled, finished with 3 to 4 ins. of 2-in. whinstone; ready for carpeting after three months.

Sett Paving.—Guildford High Street in the London-Portsmouth main road. Laid November 1867: lasted till 1927, being turned after 48 years' service.

Concrete.—Surrey: reinforced concrete, 8 ins. thick, 5 ins. between the upper and lower reinforcement, bars ½-in. diameter (usually) and spaced 9 ins. both ways in the grille; cost about 10*s.* per sq. yd.

Barnoldswick, West Riding (1928 programme): 16 streets in reinforced concrete; also 17 private streets. Clacton: in one year, 50,000*l.* spent on concrete roads, private streets. Thurnscoe, Yorkshire: concrete carriageways, 26,000 sq. yds.; cost, nearly 8*s.* per sq. yd. Example—layer of ashes; bottom course, 4 ins. of 1 : 2 : 4 gravel concrete; upper course, 4 ins. of 1 : 1½ : 3 granite concrete. Main roads reinforced with 9-in. or 12-in. square mesh, $\frac{5}{16}$-in. steel rods. Irish Free State (*J. Quigley*): concrete, one-coat, 6 ins., reinforced with wire mesh 4·8 lbs. per sq. yd. Proportions, 1 : 1½ : 3. Cost, 12*s.* per sq. yd. In good condition after three years; only maintenance treating joints with bitumen. County Wexford; Enniscorthy and Wexford Road: 11½-in. concrete.

Ilford, 1929: carriageways 20 ft. wide between kerbs, reinforced concrete slabs 50 ft. long and 22 ft. 6 ins. in bottom width; single reinforcement; laid on 3 ins. of clinkers. Cost per sq. yd., excavation, 1*s.*; clinker, 6*d.*; concrete and reinforcement, 7*s.* 6*d.*; treating the surface with silicate of soda, 6*d.*; total, 9*s.* 6*d.*

Concrete Foundation Work.—Lytham St. Anne's, housing roads over very bad ground, peat subsoil; excavation 6-ins. below crust proper; 6-ins. of destructor clinker placed to contour; 4-ins. of 2-coat concrete, 1 : 2 : 4, of 1½ to ⅝ Millstone grit and ¼-in. down pit sand; ordinary cement, fabric reinforcement; two treatments with silicate of soda. Bideford, Northern Road deviation, 7-in. local gravel concrete, 2-in. wearing surface of basalt chipping concrete, fabric reinforcement, top and bottom in some places.

Cement Grouting.—Rapid hardening cement; the dry spreading and watering system, on an upper course 2½ ins. to 3 ins. of local gravel, 1*s.* 5½*d.* per sq. yd. Another case, same system, 3-in. crust of hard broken limestone, 2*s.* 4*d.* per sq. yd.

Broken stone crust, 4 ins. to 4½ ins., cement grouted and rolled; cost, 3*s.* 4*d.* per sq. yd.; good results. Buxton Hill, cement grouted crust, gradient 1 in 7.

Gladwell System (Application of).—A method which, in principle is that known as the 'Gladwell System,' has been followed at Kirkcaldy, using cement mortar (*A. Walker*). Road scarified to 3 ins. if necessary; rolled and formed to 1 in 32; a 2½-in. layer of whinstone, 1½ to 2½ in. gauge, is rolled, the roller passing twice over every part; a mortar, 2 parts of clean sand to 1 part of rapid hardening cement, spread to about 1½ in. thick; a 2½-in. layer of stone spread over it; the whole rolled until the mortar comes to the top; surplus slurry brushed forward. This forms a good holding surface for horses. For 200 sq. yd., 26 tons of cubical stone, 1½ ins. to 2½ ins., 5 cu. yd. sand, 52 cwt. rapid hardening cement. Cost of the surfacing only, 3*s.* to 4*s.* 6*d.* per sq. yd.

Brick Paving (H. Boot, 1924).—Typical case with bricks at 6*l.* per 1,000 and bituminous joints, 8*s.* 9*d.* per sq. yd.; bricks, 5*s.* 9*d.*; jointing, 1*s.*; labour and other charges, 2*s.*; cost at Keighley, 8*s.* per sq. yd.

Brick Paving, experimental. Wolverhampton-Walsall main road, concrete foundation, blue brick on edge. North Midlands, (1) Birmingham, wire-cut blue brick on concrete strength crust, floated ¾-in. sand-cement; joints grouted 1½ to 1 mortar; laid Sept. 1922; (2) Stone-Newcastle, Class I. main road, very heavy traffic; 7-in. to 8-in. 6 to 1 concrete strength crust; 9 ins. by 4½ ins. by 3 ins., common blue wire-cut bricks on edge, laid 1922; (3) Wolverhampton-Stourbridge, Class I. main road, two test lengths laid 1923 and 1925; (4) Walsall-Wolverhampton, Class I. main road, 3,000 sq. yds. blue brick grouted with cement, on concrete strength crust; (5) West Bromwich, Class II. road; exceptionally heavy steel-tyred traffic. From a report by J. E. Swindlehurst, M.Inst.C.E., on inspection in the summer of 1926. Relating to (1) little signs of wear under heavy traffic; (2) speaking broadly, surface good after 3½ years; (3) generally in a good state; (5) indications of wear after 3 years.

Cold Emulsion Work. *Oxfordshire* (C. E. Dolphin).—Surfacing main roads with field flints and gravel, the flints from the Chiltern Hills, the gravel from the Thames Valley; flints, 3-in. downwards, hand-picked from fields, cost 5*s.* per cu. yd., laid to depth of 3 in. on the scarified road crust, all shapes together; watered and rolled; bound by grouting with cold emulsion, ¾ gallon per sq. yd., or 1 gallon per 1½ sq. yd.; covered with ⅜-in. shingle, 160 sq. yd. per cu. yd.; traffic for a few days, then a sealing coat of emulsion, ¼ gallon per sq. yd.; blinded with fine sand and rolled. Costs, per sq. yd.: flints 8·5*d.*, shingle 0·75*d.*, sand 0·54*d.*, roller and horse hire 2·41*d.*, labour 0·3*d.*, grout 8·25*d.*, sealing coat 2·75*d.*; total, 2*s.* 2·2*d.* A similar but cheaper process is also employed. For roads carrying up to 600 tons per day, a gravel, shingle, sand, grout, sealing coat road costs 1*s.* 11·3*d.* per sq. yd.

Hampshire.—Emulsified bitumen, 2·42*d.* per sq. yd., cost of grouting a limestone road; total average cost, including the sealing, 4*s.* 1¼*d.* per sq. yd.

Herefordshire.—Cold emulsion used all the year round for repairing potholes. Also used for surface dressing. Hot materials employed also.

Somerset.—Waterbound flint crust; swept clean; patched with cold dressing; tarred topping spread, 22 sq. yds. per ton; bituminous emulsion applied, ½ gall. per sq. yd.; blinded with ½-in. chippings; cost of this work on the existing flint crust, 3*s.* 0⅝*d.* per sq. yd.

Metallic Powder.

A finely ground metallic powder ('Sal-ferricite'), largely composed of pure iron, has recently been employed for hardening roads, the cost of surface hardening at Bexley Heath and Teddington being about 8*d.* per sq. yd. It has also been used to harden a surfacing about 2 ins. thick in Barcelona.

General Data.

Cheshire (W. Holland, 1924).—30-ft. carriage-way only, per mile: granite paving on concrete, 30,000*l.* (life, 30 years or more). Asphalt on concrete, 20,000*l.* (life of surface, 20 years). Two-coat bituminous surface on existing foundations, 13,000*l.* (life, 20 years). Reinforced concrete, 10,000*l.*; surface limited life, foundations, 30 years or more. Tar macadam, tar-sprayed, 5,280*l.*; life, 10-12 years. Water-bound macadam, 2,200*l.* (life with light traffic, 12 years or more).

Generally (E. S. Sinnott, 1924).—Per sq. yd.: 4½-in. water-bound limestone macadam, 2*s.* 4*d.*; 4½-in. water-bound granite macadam, 3*s.* 9*d.*; 4½-in. tarred slag or stone macadam, 5*s.* 2*d.*; 4½-in. tarred bituminous macadam, 5*s.* 6*d.*; 6 to 9 in. concrete, plain or reinforced, 9*s.* 6*d.* to 12*s.* 6*d.*; 2-in. asphaltic carpet, 6*s.* 6*d.* to 8*s.* 6*d.*; 4½-in. asphaltic macadam, 9*s.* 6*d.*; 4½-in. asphaltic part base and part carpet, 13*s.* to 16*s.* Asphaltic carpet, 2-in., on concrete or reinforced concrete base, 16*s.* to 20*s.* Wood block paving on concrete, 22*s.* 6*d.* to 31*s.*

Top Courses and Carpets.—British report to Fifth International Road Congress: bituminous and asphaltic work; ordinary costs, with five years' maintenance included: 2-coat work, 4-in., 11*s.* 6*d.* to 13*s.*; single-coat, stone and sand aggregates, 3-in., 9*s.* to 10*s.*; 2½-in., 8*s.* to 9*s.* 3*d.*; 2-in., 6*s.* 6*d.* to 7*s.* 6*d.*; clinker, 2-coat, 3-in., 7*s.* 6*d.* to 8*s.* 6*d.*; single coat, 2-in., 6*s.* 3*d.* to 7*s.* 3*d.*; mastic, 2-in., 8*s.* 9*d.* to 10*s.* 6*d.*; compressed rock asphalt carpet, 12*s.* to 15*s.*

Proportions of Surfacings.—Somerset: Classified roads and urban main roads; asphaltic and bituminous, 13 miles; tarmacadam, 155 miles; waterbound granite, limestone, and other stone, so classed, 540 miles; waterbound flint or gravel, 37 miles; other materials, 12 miles.

Surface Dressing.

Area covered.—The area covered by a gallon of tar is seldom less than 6 or more than 8 sq. yds. The cost varies with the local price of tar, an ordinary rate being 2*d.* to 3*d.* per sq. yd.
Norfolk, 5·6 sq. yd.; bitumen, 4·0 sq. yd. Hampshire, hot bitumen, 7·32 sq. yd.

Related Data.—Hampshire county roads: surface tarring, hot; 8·74 sq. yd. per gal., 1·850*d.* per sq. yd. Area, sq. yd., per man-hour, tarmacadam surfaces, 90·8; other previously treated surfaces 86·3, surfaces not previously treated 44·5; average, 83·9. Cold emulsion of bitumen, 3·82 sq. yd. per gal. Kenilworth (1928–1929): tar-spraying; 6 sq. yds. per gal.; 125 sq. yds. per ton of granite chippings, rolled in; 3½*d.* per sq. yd.

Surface Tarring.—Evesham and Pebworth rural district, 3·6*d.* per sq. yd. Somerset, county roads, 3·3*d.* Essex, average of costs of dressings, 2·82*d.* Warwickshire, tar-spraying, 2·87*d.*, 7·38 sq. yd. per gal. Staffordshire, 2·92*d.* London: average of 9 boroughs, 2·4*d.*; greatest, 3·37*d.*; least, 1·63*d.* Hammersmith (6·94 sq. yd. per gal.; cost 2·51*d.* per sq. yd. in 1920); 1926, 8·4 sq. yd. per gal., cost 1·87*d.* per sq. yd.; 1927, 1·63*d.* Durban, 6*d.* per sq. yd. Port Adelaide, tar-dressing: roadways, 4*d.*; footpaths, 2½*d.* Hampshire: tar, 1·9*d.*; bitumen, 2¾*d.* 1928–1929: Holland, Lincs., 3·51*d.*

Northants, surface dressing, 3·8*d.* Deptford, 2·51*d.* Warwickshire, 1927, 161*l.* per mile of road, surface dressing. Hampstead, hot bitumen dressing, 2·71*d.* per sq. yd. Taunton Rural District, surface dressing, contract, 3¼*d.*

Glasgow, 1927–1928, surface treatment, with chippings; 60 per cent. No. 1 tar and 40 per cent. bitumen; 5·29*d.* per sq. yd.; also, 60 per cent. No. 2 tar and 40 per cent. bitumen, 5·15*d.* per sq. yd. 1928–1929: 60 per cent. No. 1 tar and 40 per cent. bitumen, 4·54*d.*

State of Victoria: double coating, 8·59*d.*; single coating, 5·28*d.*; average on various surfaces.

Analyses of Tarring Costs.

Dorking.—Tar-spraying: manual labour, 17·3 per cent.; team labour, 16·7 per cent.; tar, at 7½*d.* per gallon, 33 per cent.; grit (at about 1 ton per 30 gallons of tar, cost 14*s.* 1*d.* per ton), 25 per cent.; tradesmen's bills, 8 per cent.

Norfolk, urban, 1924 (F. Hall Smith).—Manual labour, 0·43*d.*; tar, at 7*d.* per gallon, 0·82*d.* (covering 7½ square yards); gravel, 1·48*d.* (covering 150 sq. yds. per load); tools and establishment, 10 per cent. Total, 1·85*d.* per sq. yd.

Consett, Durham, 1929 (T. Hutton): Hot work; tar at 5½*d.* per gal., 5 sq. yds. per gal.; limestone chippings at 14*s.* 1*d.* per ton, 127 sq. yds. per ton; cost: chippings, 1·34; tar and bitumen, 1·12; labour, 0·72; transport, 0·21; plant, etc., 0·05; total, 3·44*d.* per sq. yd.; Cold work: emulsion at 9d. per gal., 4½ sq. yds. per gal.; chippings, 115 sq. yds. per ton; cost: chippings, 1·44; emulsion, 2·31; labour, 0·52; transport, 0·21; plant, 0·05; total, 4·53*d.* per sq. yd.

1927–29.

Deptford, Urban, 1927 (H. Morley Lawson).—Pence per sq. yd.: Tar, or other dressing material, 0·286; chippings, 0·503; wages, 0·314; cartage, 0·325; coke, oil, repairs and sundries, 0·078; total, 1·506.

Analysis of Cost, 1924 (A. H. Prince).—Per cent., tar or bitumen, 53; haulage, 25; labour, 12; grit, 8; sundries, 2.

Areas and Mileages, in a year:—

Kent.—1924–1925: the county spent 48,000*l.* on surface treatment, besides contributing 16,000*l.* towards the costs of similar work by urban authorities. *Worcestershire.*—Spent 35,394*l.* on tar painting. *Norfolk.*—5,337,000 sq. yds. treated with tar and 1,180,000 with bitumen, using nearly 944,000 gallons and 259,000 gallons respectively. *Essex*, used 959,000 gallons of tar. *Hampshire*, 392 miles of water-bound main roads are surface dressed.

Emulsified Bitumen.—Applied instead of tarring: Hampshire, 3·28*d.* per sq. yd.; Axbridge rural district, (*a*) first dressing, October, 3·9*d.*, second dressing, in the following May, 3·7*d.*, with chips; (*b*) first dressing, in January, 5·0*d.*, second dressing, with chips in the May following, 5·8*d.*; Bedford, single dressing, 1·86*d.*

Road Machinery.

Concrete Mixers.—From makers' descriptions. Portable concrete mixers, rated as 5 cwt. or 6 cu. ft. capacity, petrol engine, loading skip; output, 25 tons per day or more. Portable mixer, rated as 7 cu. ft., chain drive, interchangeable axles, 3½ h.p. engine. A 5-h.p. mixer, output up to 80 cu. yd. per day. A tilting drum mixer, paraffin engine, 30 to 32 batches of 3½ cu. ft. per hour.

Tar-Macadam Plant.—Drying and mixing plants, 34 to 200 tons per day, range of sizes; others, up to 200 tons per day.

Asphalt-making Plant.—Average on one job, 6½ tons of 2-in. carpet; best day's work, 7½ tons per hour. A 10-ton portable plant, output 1,000 sq. yds. of 2-in. bituminous carpeting in an 8-hour day.

Roadside Excavator.—For road widening work; cut, 18 ins. wide up to 2 ft. high; speed, 30 linear yds. per minute (presumably average soil); may be adjusted to work below road level, or above (up to 18 ins.), and below at the same time; can be fitted to any tractor or roller.

Pneumatic Spade.—A tool on the principle of a pneumatic riveting and chipping machine is the pneumatic spade.

Tar-spreading Machines.—Barnes machine, 1,000 and 700 gal. sizes; brushes made to move to and fro while spreading the tar. Clayton tar-spreading steam wagon, 6-ton, 1,000 gal., 4 to 5 miles per hour speed, interchangeable bodies.

Road Gritting Machine.—Towed by tar-spraying machine; carries 2 to 3 tons of grit; made for various widths, normally 2 to 6 ft.; up to 9 ft. if required.

Street Sweeping Attachment.—About 2½ h.p.; speed, 6 to 8 miles per hour; 6-ft. track; brush 7 ft. long by 20 in. diameter; 70-gal. water tank; two sprinkler nozzles.

Compressed Air Data.—At pressures up to 120 lb. per sq. in.; 100 cu. ft. of air per minute will operate any of the following: 2 rock drills, 2 road chisels, 5 riveting hammers.

Tar-spraying.—Steam vehicles, for whole process, capacities up to 6,000 yards per hour.

Breaking up Concrete.—Machines for breaking up old concrete foundations; 6 to 10 cubic yards per hour on a 12-in. crust.

Crawler Excavator.—Weight, 15 tons; tools; shovel, dragline, grab, back-acting trencher skimmer, scoop, crane; petrol-paraffin engine, 4-cyl., 32 b.h.p. (or steam or electric), 1 to 1¼ gal. of paraffin per hr.; 3 digs per minute when working shovel.

Trench Pump.—With suction head 15 ft., 7,000 gal. per hr., with total head 50 ft., 5,000 gal. per hr.; 4-in. suction hose, 2½ h.p.

Petrol Hoist.—Petrol or paraffin; 4-cyl., 20 h.p., pulls 4,000 lbs. at 125 ft. per min. on each drum.

Road Rollers.

Cardiff R.D.C.—Steam roller, 10-ton, purchased 1897, sold in working order 1924; cost per annum, including overhaul and all additions and repairs, 58*l.* Depreciation, 3·6 per cent. of original cost and cost of scarifiers (1903); maintenance, 8 per cent.; total cost per annum, 11·6 per cent. Steam roller, 12-ton, bought 1905, sold 1924; depreciation 3·05 per cent.; maintenance, 7·87 per cent. Steam roller, 10–12 ton, 772*l.* Motor roller, 773*l.*

Working Costs.

Somerset County Council (E. Stead).—Steam rollers, 1*l.* 9*s.* 9*d.* per day. Analysis, percentages: wages, 40·47; coal, 31·04; oil, 2·38; repairs and renewals, 15·57; sundries and insurance, 1·31; depreciation, 9·30. Petrol rollers, 1*l.* 1*s.* 2*d.* per day. Analysis: wages, 49·26; petrol, 24·68; oil, 2·77; repairs and renewals, 11·66; sundries and insurance, 1·03; depreciation, 10·60.

Warwickshire.—Steam rollers; 13 rollers; average days worked, 231; cost per day, *not* including depreciation or interest, 1*l.* 7*s.* 3*d.* Hired rollers, consolidated road metal at the rate of 1*s.* 11·6*d.* per ton. Holland, Lincs., cost per day, 1*l.* 8*s.* 9*d.*

Northants.—Cost of consolidation of road metal by steam rolling, per ton: 1926–1927, 1*s.* 4*d.*; 1927–1928, 1*s.* 1½*d.*; 1928–1929, 11·65*d.*

Holland, Lincs.—1928–1929, 8·83*d.*

Horse Haulage Costs.

Southport.—Refuse collection, cost per house (or other premises) cleared, per annum, 11*s.* 6*d.*

Warwickshire.—Haulage from wharves and railway stations, 6*s.* 5*d.* per ton; 2*s.* 3*d.* per ton-mile.

Hampshire.—14*d.* per ton-mile.

Camberwell.—4 tons per day, distance 10 miles, cost per ton-mile, 8·7*d.*

Newcastle-on-Tyne.—Refuse collection, cost per bin emptied, 2·31*d.* (compared with steam 2·16*d.*, and petrol 2·03*d.*).

Lincolnshire, 1925.—Cart, horse, and driver, 11*s.* per day. Durham 13*s.* Another county, hire of horse and wages of carman, 4*l.* 4*s.* per week.

Durban.—Single-horse cart, 9*s.* 6*d.* per day; 3-mule carts, working under different conditions, 18*s.* per day; up to 1 mile hauls both cost about 1*s.* 4*d.* per ton.

Haulage Costs.

(See also p. 759.)

From wharves to jobs, country road work, 5*s.* 10½*d.* per ton. Steam wagons, 9·7*d.* per mile (compared with petrol wagons, 9·3*d.* per mile).

Refuse Collection, 1923.—Working cost 4*s.* 3*d.* per ton when total cost was 7*s.* 10*d.* per ton. A comparison (in the same town): *horsed vehicles*, by day 8*s.* 7*d.*, by night 8*s.* 7½*d.*: *motor vehicles*, by day 7*s.* 11½*d.*, by night 8*s.* 10½*d.*, all per ton. 1924. Per ton: motor vehicles 12*s.* 4*d.*; horsed vehicles 13*s.* 8*d.* Under some conditions the difference is greater. In a number of cases under different conditions to these horsed vehicles cost less. 1926–1927. Leighton Buzzard, 4*s.* 10½*d.* per load, 3*s.* 8*d.* per ton. Deptford: public cleansing vehicles, all 3–4 ton end tipping, six comparable vehicles selected, costs ranged from 10*d.* to 1*s.* 8*d.* per ton-mile; mean, 14*d.* nearly. At Coventry, the 'Pagefield' system, cost 10*s.* per ton, has saved 2,000*l.* in one year, working 118 streets per week.

Deptford, 1927–1928 (H. Morley Lawson).—Road sweepings, 3–4 ton tipping lorry; average weight per load, 3 tons; mileage, 6,932; petrol per day, 4·49 gal.; miles per gal., 5·23; cost per day, 2*l.* 5*s.* 4*d.* Dust and road sweepings: 3-ton low-loading lorry; average weight per load, 3 tons 2 cwt.; mileage, 1,774; petrol per day, 2·22 gal.; miles per gal., 6·72; cost per day, 2*l.* 15*s.* 6*d.* Road materials: 3–4 ton tipping lorry; average weight per load, 2 tons 6 cwt.; mileage, 5,863; petrol per day, 4·23 gal.; miles per gal., 4·59; cost per day, 2*l.* 5*s.* 4*d.* Dust, road sweepings, and materials, five vehicles, 3–4 ton 'Halley' tipping lorries; average weight per load, 2 tons 14 cwt. to 3 tons 1 cwt.; mileages, 1,877 to 2,472; petrol per day, gal., 4·29, 4·70, 4·73, 4·83, 6·41; mean, 5·0. Miles per gal., mean, 3·1; cost per day, mean, 2*l.* 7*s.* 0*d.*; costs per ton-mile, pence, 11½, 14½, 16¾, 19¾, 26; mean, 17·7.

HAULAGE OF ROAD MATERIALS.

Hampshire.

(W. J. TAYLOR, M.Inst.C.E., County Surveyor: Annual Report.)

(The 'legal loads' were not exceeded.)

Hydraulic Tipping Steam Lorries.—Four of 3¼, 3½, 3¾, and 4¾ tons legal loads. Average ton-mileage, 13,740; average cost per ton-mile, 8·93*d.*; highest, 10·34*d.*; lowest, 7·25*d.*

Screw Tipping Steam Lorries.—Four of 3½, 3¾, 3¾, and 3⅞ tons legal loads. Average ton-mileage 14,500; average cost per ton-mile, 7·82*d.*; highest, 9·1*d.*; lowest, 6·6*d.*

Non-Tipping Steam Lorries.—Three of 4, 4, and 4⅜ tons legal loads. Average ton-mileage, 13,307; average cost per ton-mile, 8·91*d.*; highest, 10·9*d.*; lowest, 6·5*d.*

Eleven Steam Lorries.—As above, average ton-mileage, 13,897; average cost per ton-mile, 8·265*d.*

Petrol Lorry, Non-Tipping.—3½-ton, ton-mileage, 20,125; cost per ton-mile, 7·46*d.*

One-ton Petrol Lorries.—Three, average ton-mileage, 8,150; average cost per ton-mile, 8·23*d.*

The costs per day for steam vehicles ranged from 1·31*l.* to 2·17*l.*; average, 1·62*l.* For the 3½-ton petrol vehicle, 2·28*l.*; for the 1-ton trucks, 1·11*l.*

NOTE.—The full table in Mr. Taylor's Report should be consulted, or p. 550 of the July 1926 issue of the *Surveyor*. The figures show in a remarkably clear manner the effects upon costs of the factors:—

(*a*) Ton-mileage and (*b*) empty mileage to full mileage. Considering the range of vehicles and of loads, the degree of conformity with these factors included is notable. No exhaustive study has been made to find the critical figures of basic comparison, but there is a special significance in a portion of the cost, amounting to about 4·5*d.* per ton-mile. Taking this figure and a basic ton-mileage of 14,000, the probable cost in pence per ton-mile for any of these vehicles is indicated by some such formula as:

$$\left(4{\cdot}0 + 4 \times \frac{14{,}000}{\text{ton-mileage}}\right) \times \frac{\text{empty mileage}}{\text{full mileage}}$$

This tentative formula, or qualifier, gives the following results: 9·8 against 10·34 actual; 7·4 against 7·25; 7·03 against 9·1 (relatively few working days); 6·6 against 6·6; 10·5 against 10·9; 7·03 against 6·5; total for steam vehicles, 7·82 against 8·27 actual; petrol vehicle 6·78 against 7·46; 1-ton trucks, 8·16 calculated against 8·23 actual.

See WORKING COSTS DATA, p. 756.

Public Service Vehicles: Prices, 1926–1928.

Motor Fire-engines.—1,400*l.*, 1,125*l.*, 1,050*l.*, 725*l.* Motor-cycle fire engine outfit, 300*l.*

Motor Ambulances.—770*l.*, 700*l.* 20–25 h.p., 710*l.* Others, 650*l.*, 255*l.*

Tipping Wagons.—Steam, 3-way, 945*l.* Clayton 6-ton, end-tipping, 885*l.*

Refuse-Collecting Vehicles.—Several types, 580*l.* to 600*l.*; 560*l.*; 1,070*l.*

Gully-Emptying Vehicles.—Steam, 1,050*l.*, several types about 1,000*l.*

Motor Cesspool Emptier.—1,390*l.*

Motor Lorries.—425*l.*; 1-ton, 240*l.*; 1-ton Ford, 225*l.*; light motor van, 200*l.* Dennis, 3½-ton, 735*l.*; 2½-ton, 700*l.*; 'Pagefield' refuse-collecting lorry, with 5 containers, 2,046*l.*; tipping lorry, 30-cwt., 350*l.*; 6-ton motor wagons, 1,130*l.*

Steam Wagons.—700*l.*; 6-ton, 745*l.*

Freighters (S. D.).—572*l.*; dustcart, 'dustless' type, 7 cub. yd. capacity, 683*l.*; end-tipping, 634*l.*

Tractor and Trailer.—For refuse collection, hydraulic tipping tractor, 8½ cub. yd. capacity, 477*l.* for the unit; extra trailers, each 190*l.*

Street Sweepers.—Rotary sweeper, 578*l.*; 487*l.* Sweeper, sprinkler, and collector, 1,000*l.*; 984*l.* Sweeper and sprinkler, 850*l.* Street washing machine, 1,300 gal., 1,075*l.*

Motor Omnibuses and Coaches.—Urban type, 1,250*l.*, 1,144*l.*; single-deck, 6-wheeled, 1,200*l.*; 26-seater, saloon, 1,150*l.*; 20–24 seater, 1,070*l.*; 20–26-seater, 995*l.*; 16-seater, 795*l.*; chassis for 32-seater, 780*l.*; chassis, 14-seater, 375*l.* 18-seater, 535*l.*; 20-seater, 735*l.*

Tram-cars.—Single decker, 2,455*l.*

Footpath Roller.—Motor roller, 1¾-ton, convertible to lawn mower, 262*l.*

Vehicles and Road Plant for 442 Miles of Main Roads, Worcestershire.

(*C. B. Hammond.*)

(*To deal with heavy post-war arrears of work.*)

Fifteen 5-ton steam waggons; two 3-ton petrol waggons; one light works lorry: six motor cycles and side-cars, for divisional surveyors; five trailer waggons for the 5-ton lorries; thirteen steam rollers, 8-ton and 10-ton; two light patching rollers, with trailers; twenty-eight sleeping vans; eighteen water carts; seventeen horse-drawn tar-painting machines; ten hand-drawn tar-painting machines; thirteen horse brooms.

Equipment for Refuse Collection.

Gosport (population 3,400, area 3,998 acres). Vehicles, one Fordson tractor; three covered, 2-wheeled, 2-ton trailers; one 1-ton Ford van, sundry horses—method, horses collect only, tractor plies with trailers to and from the destructor. Cost per ton, 7*s.* 8*d.* Collection twice a week.

New Road Construction: Rates.

(*W. P. Robinson, Surrey.*)

Surface excavation not exceeding 12 ins. deep and run to tip, 8*d.* per sq. yd.; excavation to formation, hauling any distance, shaping, formation and trimming slopes, 2*s.* 8*d.* per cub. yd.; reinforced concrete post and wire fence, 4 ft. 6 ins. high, including straining posts and all fittings, 3*s.* 3½*d.* per lin. yd.; provide, spread and roll clinker, 3 ins. thick, to formation, 10*d.* per sq. yd.; concrete in carriage-way, 8 ins. thick, excluding reinforcement, laid and finished, 7*s.* 9*d.* per sq. yd.; single layer reinforcement, weight 5 lbs. per yd. laid, and including all jointing, laps, etc., 1*s.* 3*d.* per sq. yd.; double layer reinforcement, weight 10 lb. per yd., laid and including joints, laps, etc., 2*s.* 2*d.* per sq. yd.; 10 in. by 6 in. concrete kerb bedded and jointed in cement mortar to carriage-way, 5*d.* per lin. yd.

Tree Planting.

(*R. M. Morton.*)

Rosyth.—Average cost of the tree, 1*s.* 2½*d.*; limes, 1*s.* 7*d.*; chestnuts, 1*s.* 6*d.*; Lombardy poplars, 9*d.* Handling, transport and planting, 3*s.* 3½*d.* per tree; total cost per tree, 4*s.* 6*d.* Relates to 2,721 trees.

Dunfermline.—Total cost per tree, 2*s.* 7*d.* Relates to 210 trees.

Essex.—Programme of tree-planting on arterial roads; estimate, 6,000*l.*; probably at the rate of 500*l.* per annum.

Standard Trees for Roads and Hedges.

[Based on information supplied by Lt.-Col. H. V. Lane, Lane's Nurseries, Berkhampstead.]

For Roads.—(i) Planted 60 ft. apart. Height of tree: Common ash, common beech, chestnut, lime, plane, poplar, sycamore, 8 to 12 ft.; oak, 7 to 10 ft.; elm, 6 to 10 ft.; walnut, 6 to 8 ft.; purple beech, 5 to 7 ft.

(ii) Planted 20 ft. apart. Height of tree: Maple and mountain ash, 8 to 10 ft.; acers and thorns, 6 to 7 ft.

For Hedges.—(iii) Planted 1 ft. apart, 3 to 3½ ft. in height: beech, hornbeam, privet. (iv) Planted 7 to the yard: thorn (quick), 2½ ft. high. (v) Planted about 2 ft. apart, 3 to 4 ft. high, holly, yew, box, and cypress.

Costs per Mile of Road.—Basis for independent calculation: per penny per tree, 7*s.* 4*d.* per mile; per shilling per tree, 4*l.* 8*s.* (vi) Single line of trees, stakes at 9*d.* each: at 2*s.* 6*d.* per tree, 14*l.* 6*s.*; at 3*s.* per tree, 16*l.* 10*s.*; at 3*s.* 6*d.* per tree, 18*l.* 14*s.*; at 4*s.* per tree, 20*l.* 18*s.*; at 4*s.* 6*d.* per tree, 23*l.* 2*s.*; at 5*s.* per tree, 25*l.* 6*s.*; at 5*s.* 6*d.* per tree, 27*l.* 10*s.*; at 6*s.* per tree, 29*l.* 14*s.*; at 6*s.* 6*d.* per tree, 31*l.* 18*s.*; at 7*s.* per tree, 34*l.* 2*s.*; at 7*s.* 6*d.* per tree, 36*l.* 6*s.*

(vii) *Hedges*, such as (v) (above), taken as 2 ft. apart; as stakes are not required, other spacings are in proportion: for *single hedge*, at 2*s.* 6*d.* per tree, 330*l.*; at 3*s.*, 396*l.*; at 3*s.* 6*d.*, 462*l.*; at 4*s.*, 528*l.*; at 4*s.* 6*d.*, 594*l.*; at 5*s.*, 660*l.*; at 5*s.* 6*d.*, 726*l.*; at 6*s.*, 792*l.*; at 6*s.* 6*d.*, 858*l.*; at 7*s.*, 924*l.*; at 7*s.* 6*d.*, 990*l.*

(viii) *Hedges*, such as (iii) (above), taken as 1 ft. apart, other spacings in proportion; double the values in (vii).

Quickset Hedge (thorn).—Taken as 7 to the yard: at 5*l.* per 1,000, 61*l.* 12*s.*; at 7*l.* 10*s.* per 1,000, 92*l.* 8*s.*; or, with a per yard and b shillings per 1,000, the cost of *one* hedge is $£\frac{a \times b \times 88}{1000}$.

Watford By-pass Road.—Planted with beech, birch, and sycamore. The choice of beech and sycamore, especially the latter, has been adversely criticised.

Charing, Kent.—North and south by-passes: mountain ash, wych-elm.

Hampshire.—Main road, 1928–1929: 800 trees planted at widenings and on treeless stretches of road; species, the same as those growing near; regular rows avoided, planting in irregular clumps.

WORKING COSTS DATA FOR VEHICLES.

(See also p. 756.)

Steam Wagons and Lorries.

Steam Wagons.—Per day, 2*l.* 15*s.*; per loaded mile, 5*s.* 7*d.*; per mile, 2*s.* 9*d.*; per ton of load, 5*s.* 1*d.*; per ton-mile, 1*s.* 2*d.* Depreciation, 14 per cent.; wages, 40 per cent.; coal, 15 per cent.; repairs and renewals, 12 per cent.; tyres, 8 per cent.; sundries, 6 per cent.; oil, 5 per cent. Miles travelled in year, loaded, usually 1,500 to 2,000; unloaded, about the same. Working days: four vehicles exceeded 180, three exceeded 120 (out of nine vehicles)—these are 5 to 6-ton vehicles. Average load per journey, about 4½ tons; average distance per journey, three vehicles about 5 miles, three vehicles about 3½ to 4 miles, the other three less.

Liverpool (see 'Electric' and 'Petrol').—Steam wagons, costs: per ton, 5*s.* 5*d.*; per mile, 3*s.* 9*d.*; per ton-mile, 1*s.* 6½*d.*

Camberwell.—Steam wagon, under favourable circumstances, 1922: Running costs, fuel, 28 per cent.; oils, tools, and sundries, 5½ per cent.; licence and insurance, 4 per cent.; repairs and fittings, 5½ per cent.; wages, 53 per cent.; depreciation, 15 per cent.; tyres, 3 per cent.; or, including extra labour for loading, about half these percentages, and extra labour nearly 50 per cent. Total cost, 392*l.*; mileage, 857; cost per mile, 9*s.* 2*d.*; cost per mile without extra labour for loading, 4*s.* 7*d.* Hauling, with trailer, 26 tons per day, distance 10 miles: cost per day, 3*l.* 3*s.*; extra labour for loading, 3*l.* 2*s.*; cost per ton-mile, 5·7*d.*

Godalming.—Oil-fired steam lorries, heavy oil at 10½*d.* per gallon; six ton-miles per gallon.

Warwickshire.—Per working day, 2*l.* 17*s.* 4*d.*; tons hauled per annum, 5,273; cost per ton delivered on to the road, 2*s.* 6¾*d.*

Nottinghamshire.—For steam wagons: average age, 7 years; average load, 6·5 tons; average mileage, 447; average loaded mileage, 202·5; costs: per day, 3*l.* 7*s.* 3*d.*; per mile, 6*s.* 5½*d.*; per ton-mile, 1*s.* Depreciation at 12½ per cent. has already cleared off the cost of two of these vehicles. About three months after the end of the financial year, 1924–1925, the whole capital sum had been discharged, and the working cost per ton-mile reduced to 10*d.* 1926–1927: steam wagons and trailers; average days worked, 192; tons per journey, 6·56; cost per day, 2*l.* 14*s.* 6*d.*; cost per ton-mile, 10·2*d.*

Durban.—6-ton steam wagons, 1*s.* 4*d.* per ton-mile.

Somerset County Council (W. J. Taylor).—Steam wagons, 7 Foden and 10 Sentinel: costs, 1927–1928: per working day, 2*l.* 12*s.* 11¾*d.*; per mile, 1*s.* 7¾*d.*; per loaded mile, 3*s.* 2¾*d.*; per ton carried, 2*s.* 11¾*d.*; per ton-mile, 7·45*d.* (2*d.* less than in 1925). Working costs, percentages: wages, 46·16; coal, 13·98; oil, 3·39; repairs and renewals, 14·32; tyres, 5·01; sundries, insurance, and licence, 11·99; depreciation, 5 per cent., 5·15.

Berkshire County Council (J. F. Hawkins), 1927–1928.—Steam wagons, 3 Clayton and Shuttleworth: miles, loaded, 6,719; unloaded, 6,945; total, 13,664 (one vehicle sold, January 1928), total miles for the other two, 10,558; the three; tons hauled, 11,903; days worked, 662½; days standing by for repairs or delays, 117½; loaded journeys, 1,932; empty, 1,993; ton-miles, 41,396; average, load per journey, 6·16 tons; loaded journey, 3·48 miles. Working costs, all charges: per working day, 2*l.* 9*s.* 8*d.*; per mile, 2*s.* 5*d.*; per loaded mile, 4*s.* 11*d.*; per ton carried, 2*s.* 9*d.*; per ton-mile, 9½*d.* Total cost, 1,644*l.* 0*s.* 3*d.*; including, wages, 829*l.*; fuel, 259*l.* 5*s.*; repairs and renewals, 240*l.* 13*s.*; depreciation, 119*l.* 15*s.*

Surrey County Council (W. P. Robinson).—Four Foden steam wagons; 5-tonners; miles loaded, 15,950; unloaded 12,282; tons hauled, 11,299; days worked, 954; ton-miles, 74,307; average costs, per day, 3*l.* 16*s.* 3*d.*; per ton-mile, 11·74*d.* (see p. 760 for Surrey petrol vehicles). Reduced, relative costs, 5-ton vehicles per ton-mile; steam, 5·65*d.*; petrol, 4·87*d.* (see p. 760).

Holland, Lincs. County Council (W. A. Rogerson).—5-ton rubber-tyred steam and petrol wagons, with mechanical tipping gear; cost per ton, 2*s.* 9½*d.*; cost per ton-mile, 10·15*d.*

Electric Vehicles.

Worcestershire.—County council lorries (all costs except capital charges, depreciation, and insurance), 14·9*d.* per ton-mile.

Willesden.—2½-ton vehicles; capacity, 6 cubic yards; units per mile, 1·223; tons lifted per man-day 2·29; tons per vehicle per day, 6·28; cost (total) of collection, 11*s.* 2*d.* per ton.

Liverpool (see under 'Steam' and 'Petrol').—Cost per ton, 4*s.* 6*d.*; cost per mile, 5*s.* 9*d.*; cost per ton-mile, 3*s.* 4*d.*

Canterbury.—2½-ton vehicles: cost of electricity, per mile, 7·23*d.*; per ton, 13·7*d.*; cost of electricity, oil, water, grease, and repairs, 20·3*d.* per ton-mile. Total cost per ton-mile, including capital charges and insurance, 2*s.* 9*d.*; per working day, 6*l.* 17*s.*

Wolverhampton.—(A) Vehicles 1½ years old: kilowatt-hours, per mile, 2·22; costs—capital charges, 22 per cent.; battery, 21·6 per cent.; tyres, 2·6 per cent.; insurance, 1·6 per cent.; wages, 30·7 per cent.; repairs and maintenance, 5 per cent.; electrical energy, at 2¼*d.* per unit, 16·5 per cent.; cost per ton-mile, 10·2*d.*; cost per hour in use, 5*s.* 9*d.* (B) Vehicles 3½ years old: kilowatt-hours, per mile, 1·87; costs—capital charges, 21 per cent.; battery, 15·5 per cent.; tyres, 1·8 per cent.; insurance, 0·7 per cent.; wages, 41·6 per cent.; repairs and maintenance, 9·9 per cent.; electrical energy at 2¼*d.* per unit, 9·5 per cent.; cost per ton-mile, 1*s.* 4*d.*; cost per hour in use, 7*s.* 11*d.*

Nottingham.—October 1915 to December 1924: 3-ton electric vehicles; refuse collection. Total costs: current, 4,802*l.*; tyres, 848*l.*; battery upkeep, 453*l.*; maintenance, 3,905*l.*; licences, insurance, etc., 1,678*l.*; depreciation, 13,893*l.*; total upkeep, 25,597*l.*; wages, drivers and mates, 46,341*l.*; grand total, 71,920*l.*; mileage, 322,797; tons, 17,631; cost per ton, 8*s.* 2*d.* Now twenty-eight such in service.

Petrol Vehicles.

Liverpool (see 'Steam' and 'Electric').—Costs: per ton, 6*s.* 7*d.*; per mile 2*s.* 8*d.*; per ton-mile, 1*s.* 7*d.* *Test*, 5½-ton lorry and trailer; tare of lorry, 4 tons 7 cwt.; of trailer, 1 ton 13 cwt.; average speed, 12 miles per hour; petrol, 5·9 miles per gallon; with nearly 11½ tons load, 60 net ton-miles per gallon; with nearly 4½ tons load, 28·5 ton-miles per gallon; average, 46 ton-miles per gallon; oil, 516 miles per gallon. Another place, 3½-ton lorry, 11 miles per gallon of petrol.

Surrey County Council (W. P. Robinson).—Six 5-tonners; miles loaded, 34,569; unloaded, 24,484; tons hauled, 21,177; days worked, 1,680; ton-miles, 162,548; average costs, per day, 2*l.*; per ton-mile, 4·95*d.* One-tonner, 14·06*d.* 1½-tonner, 17·54*d.* per ton-mile (see p. 759 for Surrey steam vehicles). Reduced, relative costs, 5-ton vehicles per ton-mile; petrol, 4·87*d.*; steam, 5·65*d.* (see p. 756).

Worcestershire.—Ford landaulette, one year, mileage, 6,844; cost per mile, 1*s.* 5½*d.* (this cost includes 'rent,' insurance, 'uniform,' etc.).

Middlesbrough.—Street-watering van: interest and redemption, 18·4 per cent.; tyres, 3·6 per cent.; repairs and renewals, 7·2 per cent.; driver, 22·6 per cent.; oils and grease, 1·4 per cent.; insurance, 1·4 per cent.; petrol (at 2*s.* 2*d.* per gallon), 38·9 per cent.; taxes, 4·3 per cent.; sundries, 2·2 per cent.; cost per day, about 2*l.* 16*s.*

Motor Haulage.—By contract, 13·57*d.* per day; by council's department, 13·40*d.* per day.

Middlesbrough.—Street-sweeping machine: interest and redemption, 10·5 per cent.; tyres, 3·4 per cent.; repairs and renewals, 6·8 per cent.; driver, 17·5 per cent.; oils and grease, 1·8 per cent.; insurance, 1·1 per cent.; petrol (at 2*s.* 2*d.* per gallon), 36·8 per cent.; refills for brooms, 17 per cent.; taxes, 3·3 per cent.; sundries, 1·8 per cent.; costs, about 7*s.* per mile, or 4⅜*d.* per 1,000 sq. yds. Street-sweeping machine, 20*s.* per mile.

Street Sweeping.—By motor sweeper, 7*d.* per 1,000 sq. yds.

Refuse and Sweepings Collection.—1*s.* per ton-mile.

Various Vehicles.

Per Day, 1925.—Steam wagons (Staffordshire County Council), 3*l.* 4*s.* 9*d.*; Nottinghamshire, 2*l.* 14*s.* 9*d.*; Somerset, 2*l.* 13*s.* Steam rollers: nine steam rollers, Warwickshire County Council, working costs only, 29*s.* 6*d.* Nottinghamshire, steam rollers, including the hauling of water, 1*l.* 14*s.* 6*d.* Somerset: steam rollers, 10-ton, working costs, 1928, 1*l.* 9*s.* 1*d.*; petrol rollers, 6-ton, 19*s.* 2*d.* Another case, 1*l.* 13*s.* 7*d.* Durham, 1*l.* 14*s.* 4*d.*

1925–1926.—Cardiff R.D.C., 1*l.* 18*s.* 6*d.*; West Riding C.C., 1*l.* 11*s.* 4*d.*; petrol rollers, 1*l.* 19*s.* 1*d.*; Somerset C.C., 10-ton steam, 1*l.* 9*s.* 6*d.*; 6-ton petrol, 1*l.* 8*s.* 6*d.*; steam wagons working costs only, 2*l.* 11*s.* 6*d.*; rotary sweepers (motor), 1*l.* 15*s.* 2*d.*; gulley emptiers, 2*l.* 17*s.* 3*d.* (per gulley, 2*s.* 9*d.*; watering van, 1*l.* 19*s.* 9*d.*; steam wagons, 3½ to 4¾ tons lading, hydraulic tipping, 1*l.* 12*s.* 6*d.*; screw tipping, 3½ to 3¾ tons, 1*l.* 14*s.* 4*d.*; non-tipping 4-ton, 1*l.* 10*s.* 5*d.*; petrol 3½-ton vehicle in the same 'fleet,' 2*l.* 5*s.* 7*d.* Torquay: refuse collection, 5*s.* 4*d.* per ton, with current at 2*d.* per unit. See under preceding classified headings.

Per Hour.—One-ton horse carts, 3*s.*; 10-ton steam rollers, 8*s.* 7*d.*; 10-ton motor rollers, 8*s.* 7*d.*; motor gully cleanser, 9*s.* 3*d.*; motor broom, 3*s.* 10*d.*—all including attendants. Electric vehicles, 3½-ton, 1½ years old, 6*s.*; the same, 3½ years old, 8*s.* 1923: steam roller (Kent), 6*s.* 3*d.* Vehicles of some years' service (Kent): steam tractors, 7*s.* 7*d.*; petrol lorries, 7*s.* 5*d.*; Foden lorries, 6*s.* 6*d.*

Kent: working expenses per hour, 4*s.* 4*d.*; steam tractors, 5*s.* 4*d.*; petrol lorries, 5*s.* 3*d.*; steam lorries, 5*s.* 9*d.*

Per mile.—Lorries, 9·44*d.*; 1-ton Ford trucks, 7¼*d.* (12·2 miles per gallon); rotary motor sweepers, 1*s.* 9*d.*; watering van, 1*s.* 11*d.*; tipping lorry, 4*s.* 2*d.*; the same, hauling road materials only, 3*s.* 2*d.*; steam waggons, 1*s.* 10*d.*, 1*s.* 9*d.*

Per ton.—Worcestershire county lorries, 2*s.* 11½*d.*; steam waggons, working costs only, 2*s.* 6½*d.* From wharves and stations to jobs, County Council, 3*s.* 4½*d.*; tipping lorry average, 5*s.* 1*d.*; hauling road materials, 3*s.* 6*d.*, 3*s.*, 2*s.* 9*d.*

Per ton-mile.—Tipping lorry, 4–5-ton, average, 1*s.* 8*d.*; hauling road materials, 1*s.* 2*d.*; steam lorry, 8½*d.*; steam lorries, capital charges paid off, 10*d.*; steam wagon, hydraulic tipping, 8·9*d.*; screw-tipping, 7·8*d.*; non-tipping, 8·9*d.*; non-tipping petrol lorry, 7·5*d.* (larger mileage).

Pembrokeshire county steam waggons (A. H. Thomas), 9·3*d.*

Birmingham (A. Baker).—Operating costs: motor omnibuses, 12 months, 15*s.* 4*d.*; tramcars, 12 months, 14*s.* 8*d.*; trolley omnibuses, 6 months, 12*s.* 6*d.* per mile.

Traffic Statistics.

Paisley-Glasgow Road, 6,796 tons per day; eight roads radiating from Liverpool, over seven million tons (less than one million in 1913); rate for July over nine million tons per annum. London, millions of tons per annum: Hyde Park Corner, estimated, 48; Hammersmith Broadway, 19; The Angel, Islington, 16. Railway statistics suggest that about 34 million tons per annum of traffic has been diverted to the roads. (*Lord Montagu of Beaulieu*, '*The Times*,' 1922.)

Main Route Traffic: Tons per Day.—The three consecutive figures are, in every case, pre-war (1910, 1911, or 1912), 1922, 1925: London-Edinburgh, near Framwellgate Moor, Durham, 636, 3,346, 5,348; London-Dover, near Newington, Kent: 568, 1,943, 4,623; London-Portsmouth, near Pease Marsh, Surrey: 790, 3,809, 6,417; London-Holyhead, near Redbourne, Herts., 508, 2,649, 4,166; Liverpool-Sheffield-Lincoln, near Sankey Bridges, Lancashire, 1,167, 8,250, 11,606. The pre-war figures are averages for the year (presumably), those for 1922 and 1925 being in August (British Report on Bituminous and Asphaltic Roads: Fifth International Road Congress, 1916). A road in Norfolk, 4,752; another, 2,326.

Christchurch, New Zealand.—1922 figures compared with 1915; per cent.; light motor vehicles, increase 37·9 in number and 58·5 in weight; heavy motor vehicles, 5·8 and 33·1; bicycles, 42·5 and 4·6; decrease, horse-drawn vehicles, horses and cattle, 13·8 and 88.

Wolverhampton.—1925-1926, Municipal transport services: tramcars, 30; motor-omnibuses, 27; trolley-buses, 16; passengers carried: trams, 15·24; motor-buses, 5·62; trolley-buses, 4·67 millions per annum.

Scotland.—Traffic census, 1922: tons per day, industrial areas, maximum 5,542: rural areas, maximum 739.

Great Britain.—About 14,000 steam waggons and road locomotives, using a million tons of coal and coke per annum.

London.—About 7,000 motor-omnibuses per day, using the Strand, Oxford St., Piccadilly, Regent St., and Parliament St., taxed at 6*d.* per bus-mile, amounting to 7,000*l.* a mile of these routes (*Shrapnell-Smith*).

Paris.—At four cross-roads, 3 p.m. to 7 p.m., during one week: averages per hour; year 1910, 1,240, 2,544, 2,613, and 2,168, respectively; year 1925, in the same order, 2,510, 4,407, 3,677, 3,005.

Average Weight.—Average weight of traffic units: summer, 1922, 1·10 tons; 1925, 1·29 tons; winter, 1925, 1·74 tons; Great Britain.

Heavy Loads.—Sheffield, 100 tons on 4 wheels, 'commonplace'; Sheffield to Birmingham, 75 tons (W. J. Hadfield).

Rate of Increase: Motor Vehicles.—Number of motor vehicles licensed, exceeded the number of the preceding year by, per cent.; 1922 to 1928; 12, 16, 17, 15, 11, 10, 8.

Transport Ministry's Return Relating to Tramway Undertakings.

A return issued (November, 1928) by the Ministry of Transport giving particulars of the tramway undertakings in Great Britain for the year ended December 31, 1927, for companies, and March 31, 1928, for local authorities, shows that during the period covered there were 233 tramway undertakings, of which 167 were owned by local authorities and 66 by companies. The route mileage worked amounted to 2,514 miles, a decrease of 40 miles compared with the previous year.

The total capital expenditure at the end of the period under review amounted to 99,913,760*l.*, an increase of 1,303,255*l.* in the year. The total gross receipts during the year were 27,751,504*l.*, and the total working expenditure 21,943,147*l.*, leaving net receipts amounting to 5,808,357*l.*

The number of passenger journeys during the year was 4,705,842,932, an increase of 5·51 per cent. compared with 1926–27. Car miles run amounted to 396,554,545, an increase of 4·70 per cent. compared with the previous year.

The return also gives particulars of the working of trackless trolley undertakings in Great Britain. At the end of the period the undertakings of twenty local authorities and one company were open for traffic, and the length of route operated amounted to 111 miles, an increase of 24 miles. The number of passengers carried increased by about 59 per cent. to 80,112,970.

ADDENDA.

District Roads: Delegation. (See p. 713.)

The number of rural district councils to which the management of unclassified roads has been delegated is 262, out of a possible 643.

The Road Traffic Act, 1930.

Generally, the Act repeals all legislation which might have been incompatible with its provisions in respect of the control of traffic and regulations for vehicles and loads.

New Classification of Motor Vehicles.

Motor vehicles are now grouped in the classes:

Heavy Locomotives, not load carrying, the unladen weight exceeding 11½ tons.

Light Locomotives, not load carrying, unladen weight 7½ to 11½ tons.

Motor Tractors, not load carrying, unladen weight not exceeding 7½ tons.

Heavy Motor Cars, not being vehicles classified under the section as Motor Cars, unladen weight exceeding 2½ tons.

Motor Cars, not being motor cycles nor invalid carriages: (1) constructed solely for the carriage of passengers and their effects; adapted to carry not more than 7 passengers besides the driver; fitted with tyres of the prescribed type; weight not exceeding 3 tons; (2) in any other case, not exceeding 2½ tons.

Motor Cycles, having less than 4 wheels, the unladen weight not exceeding 8 cwt.

Invalid Carriages, specially designed as such and solely so used, unladen weight not exceeding 5 cwt.

Regulations.—Provision may be made by regulations (1) for sub-division of the above classes and making different provision for each sub-division, varying, as respects any class, the maximum or minimum weight.

Regulations under the Act.

The Motor Vehicles (Construction and Use) Regulations, 1931, and the Motor Vehicles (Authorisation of Special Types) Order (No. 1), 1931; in force from January 15, 1931.

The Regulations repeal 26 Orders made under the Locomotives on Highways Act, 1896, relating to heavy motor cars and motor cars, and supersede the Locomotives Acts in respect of the construction of locomotives. Manufacturers and owners should refer to the Orders for detail as to time limits and exemptions.

Provisions as to Tyres.

Subject to a few exceptions:

(1) On and after January 1, 1933, locomotives and tractors and their trailers must be fitted with pneumatic or with rubber tyres; (2) heavy motor cars and motor cars exceeding one ton in weight unladen; (*a*) registered after January 1, 1933, must be equipped with pneumatic tyres, (*b*) must all be so equipped by January 1, 1940; (3) every trailer constructed after January 1, 1933, drawn by a motor car or heavy motor car, must be equipped with pneumatic tyres, and all such must be so equipped by January 1, 1940. Exemptions, (*a*) land implements, agricultural trailers; (*b*) constructed before January 15, 1931, and (1) designed for horses or cattle; (*c*) (ii) designed for furniture and similar household effects.

The maximum width, 7 ft. 6 ins., of a heavy motor car registered on or before January 1, 1932, may be exceeded by 6 ins. if this increase is necessarily due to conversion to use with pneumatic tyres.

Locomotives.—If the soft tyres obligatory after January 1, 1933, are in sections, these may not be separated by more than ¾ in., and the aggregate of spaces must not exceed 6 ins. This regulation does not apply to agricultural locomotives having smooth-soled steering wheels tyres, not less than 5 ins. tread, and driving-wheel tyres not less than 12 ins. wide, smooth-soled, or shod with diagonal bars not less than 3 ins. wide, nor more than ¾ in. thick, nor more than 3 ins. apart; nor to agricultural tractors, similarly, but steering wheel tyres 2½ ins. and driving-wheel tyres 6 ins.

Maximum Dimensions.

(Not verbatim, but sections given for reference.)

(5) Four-wheeled vehicle, 27 ft. 6 ins.; more than 4 wheels, 30 ft.; articulated vehicle, 33 ft.; 8-wheeled articulated vehicle registered before January 1, 1931, 36 ft. (20) Locomotive, overall width 9 ft. (26) Motor Tractor, width 7 ft. 6 ins. (27) Overhang, 6 ft. (31) Heavy Motor Car, width 7 ft. 6 ins. (39) Motor Car, width 7 ft. 2 ins. (32) and (40a) Overhang in both cases seven twenty-fourths of length. (51) Trailer, length, exclusive of draw-bar, 22 ft., unless normally used for indivisible loads of exceptional length, or being a land implement or part of an articulated vehicle. (52) Overall width (other than a land implement), 7 ft. 6 ins.; a trailer in use by a travelling showman before January 15, 1931, 8 ft. 9 ins.

Maximum Weights.

(21) *Locomotive.*—Unladen, 15½ tons; additional 1½ ton if having a permanent fitting such as a crane or winding drum, and, independently, 2 tons if fitted with soft tyres. Not more than three-quarters of the total weight may be carried by any two wheels.

(33) *Heavy Motor Cars.*—Four-wheeled, 7½ tons; 6-wheeled, 10 tons; more than 6 wheels, 11 tons (permanent fitting allowance as (21)).

Other Regulations.—(56) The maximum weight of a locomotive must not exceed the unladen weight by more than 3 tons.

(57) The maximum weight of all the trailers drawn by a locomotive may not exceed 40 tons.

(58) The sum of the weights transmitted to the road by the wheels of a trailer and of a tractor or heavy motor car drawing it must not exceed 22 tons.

(59) *Heavy Motor Cars.*—Maximum weights: of a single wheel in a transverse line, 4 tons; of any two of four, 8 tons; of any two of more than four, 7½ tons. Total weights: all wheels, 4-wheelers, 12 tons; 6-wheelers, 19 tons; limit, 22 tons.

Heavy Vehicles on Bridges.

The bridge authority of any bridge may, by means of conspicuous notices, prohibit the use of the bridge: (*a*) by a vehicle exceeding a defined maximum laden weight, not less than five tons; (*b*) in respect of the laden weight of a vehicle when travelling at more than a defined speed. Provision is made for appeal to the Minister, who may order a prohibition or restriction to be removed, or may refer the matter to an arbitrator.

RECENT TECHNICAL INFORMATION.

Road Tars: British Engineering Standards Association, Specification, 76—1930, and Part 2—1931.

Requirements.	Tar No. 1.	Tar No. 2.	Tar No. 3.
Specific Gravity at 15 degs. C. not less than	1·140	1·150	1·160
(See Note A) nor more than	1·225	1·240	1·260
Water or ammoniacal liquor not more than, per cent. by weight	0·5	0·5	0·5
Other distillate (light oils) below 200 degs. C., not more than, per cent., by weight	1·0	1·0	1·0
Distillate between 200 degs. C. and 270 degs. C., within the range, per cent., by weight	9·5 to 21·0	8·0 to 16·0	6·0 to 12·0
Distillate between 270 degs. C. and 300 degs. C. (heavy oils) within the range, per cent. by weight	3·5 to 12·0	3·5 to 12·0	3·0 to 8·0
Phenols or crude tar acids, not more than, per cent. by volume	5·0	4·0	2·0
Naphthalene, not more than, per cent. by weight	6·0	5·0	3·0
Free carbon, per cent. by weight	Max. 20	6·0 to 21·0	8·0 to 22·0
Consistency or viscosity Hutchinson, at 25 degs. C., within the range seconds	10–40	40–125	70–120
(But surveyors may specify higher consistencies when required.)			

Note A.—Tar produced from Scottish coals and carbonised in vertical retorts may have minimum specific gravities 1·110 for Tar No. 1 and 1·120 for Tar No. 2, provided such tar complies with the specification in all other details.

Points from Road Tar Specifications and Analyses.

Belgium, Germany, France, Sweden; percentages.—On the whole, the specifications, and the analyses of consistent and approved road tars, follow the British standards. A tar found satisfactory in Sweden has sp. gr. 1·1 and water 0·3, a Paris tar sp. gr. 1·19 and water, min. 1·0. The French departmental specification allows up to 0·75 water, also, distillate 170 to 270 degs. C., min. 12, max. 24. German road tar No. 1, phenols, max. 3·0; free carbon 5 to 16; crude anthracene, max. 3·0; viscosity, Hutchinson, for that tar 8 to 15, for a German tar called 60/40, 20 to 70; Belgium, tars 1 and 2, as the British, the Swedish tar, 52. Drop points are, Belgian 'Wetterteer," laboratory tests, 34 deg. C., German 'Wetterteer,' prescribed, min. 30 degs. C. Distillate below 170 degs. C., in Belgian 'Wetterteer,' nil, in Belgian, German and French specifications, five tars, max. 1·0. In the Swedish tar, analysis 0·2; in the Paris tar, analysis 0·6. The German specifications allow 9 to 17 and 1 to 10, distillate 170 to 270 degs. C., the analyses of the 'Wetterteers' giving, Belgian 1·9, German 1·0.

Road Planning and Design.

Building and Improvement Lines.—The adoption of 120 ft. spacing for building lines and 60 ft. for improvement lines seems to be nearly general. In some counties building lines only, and in others improvement lines only, have been prescribed.

Road Widths.—A Ministry of Transport memorandum gives, as widths to be aimed at: (*a*) for Class I roads, 60 ft.; for Class II roads, 50 ft.; but greater widths should be provided in many cases; (*b*) Normal unit width for carriageways, 10 ft., for dual roads, initial minimum unit width, 10 ft., increments 9 ft.; (*c*) footpaths, minimum 4 ft. in the open country, elsewhere, 5 ft.

Radius at Bends.

The Ministry of Transport Memorandum of August 1930 advises that where conditions are favourable, a minimum radius of 1,000 ft. should be aimed at; failing which, the width of the carriageway at the bend should be increased. Normal practice in open country in the United States is to provide 5 degs. (1,146 ft. radius) or 6 degs. (955 ft.) curves. The German reporters to the Sixth International Road Congress prescribe a minimum radius of 300 metres in level and rolling country.

The Main Highways Board of New Zealand recommend, in easy country, 6, 4½ and 3 chains (100 ft.) radius, for first, second and third class roads; in difficult country, 2, 1½ and 1 chain. Additional widths, on the inside of the bend, are given, up to 3 chains, 5 ft.; 4 chains, 4 ft.; 5 chains, 3 ft.; 10 chains, 2 ft.

Superelevation at Bends.

A convenient approximate formula for balance of centrifugal and gravity accelerations, or of centrifugal force and component of weight is:

$$\frac{h}{l} = \frac{v^2}{15 \times r}$$

where h is the height of tilt, l the horizontal width, in the same units; v the speed in miles per hour, r the radius in feet.

The reporters to the Sixth International Road Congress, October 1930, recommend the following superelevations: for radius 50 to 100 ft., 1 in 10; 200 to 500 ft., 1 in 12; 500 to 800 ft., 1 in 16; 800 to 1,000 ft., 1 in 24. The German reporters indicate 4 in 100 as normal, 5 in 100 on sharp curves and 6 in 100 where the curve is on a steep gradient. The French reporters give, for roads in Morocco, a limit of 1 in 10 on curves of short radius, and on mountain roads, where the radius r corresponds to superelevation 1 in 10 the superelevation of a curve of radius R is

$$d = \frac{r}{\mathrm{R} \times 10}$$

The Main Highways Board of New Zealand employ a formula:

$$\mathrm{C} = \frac{6 \times \mathrm{S}^2}{1000\ \mathrm{R}}$$

in which C is tilt in inches per foot, S, speed in miles per hour and R, radius in 100 ft. chains. It gives superelevations three-quarters of those for balance, and is a modification of h in inches $= l$ in feet $\times \frac{\mathrm{S}^2}{\mathrm{R}} \times \frac{4}{5}$ in which R is in feet.

The Board recommends tilts in inches per foot: 2 chains, 1½; 3 to 7 chains, 1; 8 to 15 chains, ¾; 16 to 40 chains, ½; high-class pavements not more than 1 in.

Visibility at Summits.

The Ministry of Transport Memorandum of August 1930 advises that curves of parabolic form shall be provided at all changes of gradient and be such as will provide a clear view of 50 yds. on each side of a summit to drivers of mutually approaching vehicles. In many States (U.S.A.) it is required that a 500-ft. line of sight must be provided 5 ft. above the crown of the road.

London Pavings: Recent Replacements.

From the Metropolitan Paving Committee's Report for 1929–1930.

Wood Blocks.—Presumably soft wood: (1) Creosoted deal on concrete, replaced by 2½ ins. hard clinker asphalt on 10 ins. reinforced concrete; cost of carpet and strength crust, 17*s.* 10*d.* per sq. yd. (2) 'Wood Blocks,' replaced by 3 × 6 × 5 ins. Guernsey granite blocks on 9 ins. of concrete; cost 40*s.* 6*d.* (3) Creosoted deal, laid 1915, replaced 1928 by Swedish granite setts, 5 × 5 × 4 ins. deep, on repaired old concrete foundation; cost, foundation 9*s.* 9*d.*, paving 25*s.* 5*d.* (4) 'Wood Blocks,' replaced by 2 ins. natural rock asphalt on new 5 ins. concrete; cost, foundation 6*s.* 10*d.*, carpet 14*s.* 5*d.* (5) 'Softwood,' laid 1899, replaced 1929 or 1928 by 2 ins. compressed natural rock asphalt on 10 ins. concrete, cost, foundation 14*s.* 8*d.*, carpet 10*s.* 6*d.*

Hardwood Blocks.—(1) Jarrah, 3 ins. sectional blocks, laid 1913, replaced 1928 by creosoted softwood on 12 ins. concrete; cost, of foundation 21*s.* 9*d.*, paving 15*s.* 6*d.* (2) 'Hardwood,' laid 1911, replaced 1928 by creosoted deal on 8 ins. reinforced concrete; cost, of foundation 15*s.* 2*d.*, of paving 11*s.* 4*d.* (3) Jarrah blocks, laid 1907–8, replaced 1929 by creosoted deal blocks on 9 ins. of concrete; cost of the paving 12*s.* 8½*d.*

Stone Setts.—Granite setts, laid 1910, replaced by creosoted deal blocks; cost of the paving 13*s.*

Tarmacadam and Tarslag Macadam.—(1) Replaced by 3 ins. Guernsey granite concrete on 6 ins. Thames ballast concrete; cost, the lower layer 3*s.* 8*d.*, the upper layer 11*s.* 10*d.* (2) Tarslag macadam, laid 1913, replaced by 2 ins. asphaltic macadam on 9 ins. reinforced concrete, on a bed of 3 ins. of hard furnace clinker. (3) Tarmacadam, replaced by creosoted deal blocks on 9 ins. concrete. (4) Tarmacadam, replaced by 2 ins. asphaltic carpet on the hardcore foundation; cost of carpet, 4*s.* 6*d.* per sq. yd., with 3 years free maintenance.

Waterbound Macadam:

Carpeted.—(1) With 2 ins. asphalt macadam; (2) with 4 ins. asphalt macadam; (3) with 3½ ins. bituminous grouted macadam; (4) with 2 ins. bituminous macadam; (5) with 2½ hot-laid asphalt; (6) and (7) with 3 ins. asphaltic concrete; (8) with 3 ins. asphaltic macadam; (9) with 3½ ins. tarred macadam.

Replaced.—(1) By a cold grouted limestone crust of 2½ ins. to ¾ in. grade material, cost, with foundation, 7*s.* 6½*d.*; (2) by 4 ins. tarslag macadam, on the old subcrust consolidated, cost, preparing foundation 3*s.* 7*d.*, surfacing 6*s.* 5*d.*, with three years free maintenance.

Haulage Costs. (See pp. 759–61.)

Per Ton-Mile.—Holland (Lincs.) 9*d.*; Worcestershire, 5·8*d.*; Essex, 6-ton steam wagons, 8¼*d.*, 5-ton steam wagons, 10¾*d.*, petrol lorries, 6-ton, 7¼*d.*, 5-ton, 9¾*d.*; Surrey, 5-ton steam wagons, 8·4*d.*, 5-ton petrol lorries, 5·36*d.* (average ton-mileages, steam 22,932, petrol 27,640); Aberdeen, average, 5·9*d.*; Bristol, steam, 5·2*d.* (average haul 5·56 miles, average load 4·76 tons), electric, 8·4*d.* (average haul 5·0 miles, average load 2·36 tons).

Per Vehicle-Day.—Surrey, steam, 3·137*l.*, petrol, 2·391*l.*; Essex, steam, 6-ton 2*l.* 19*s.* 2*d.*, 5-ton 2*l.* 13*s.* 5*d.*, petrol, 6-ton, 2*l.* 11*s.* 7*d.*, 5-ton, 1*l.* 12*s.* 8*d.* Other cases, 5 and 6-ton vehicles, 2*l.* 16*s.* to 2*l.* 18*s.*

Per Ton Hauled.—Holland (Lincs.), 2*s.* 3*d.*; Worcestershire, 2*s.* 1¼*d.*; county road work; steam wagons, usually well within the limits, 2*s.* 2*d.* to 3*s.*

Per Mile.—Surrey, steam, 6-ton, 1*s.* 9¾*d.*, 5-ton, 2*s.* 2¾*d.*; petrol, 6-ton, 1*s.* 5¾*d.*, 5-ton, 1*s.* 7¾*d.* Aberdeen, 1*s.* 5*d.*

SECTION XVI

ARRANGEMENT AND CONSTRUCTION OF ENGINEERING WORKSHOPS — WORKSHOP PRACTICE

(pp. 765–780)

(With Contribution by H. N. Allott, M.Inst.C.E.)

SECTION XVI

ARRANGEMENT AND CONSTRUCTION OF ENGINEERING WORKSHOPS — WORKSHOP PRACTICE

ENGINEERING WORKSHOPS.

(Contributed by H. N. Allott, M.Inst.C.E.)

For ordinary engineering purposes the arrangement of shops on one level is most convenient, as this allows of better supervision, better access between the various shops, and better light than is possible where the works are arranged in buildings of more than one storey. Multiple storey buildings are generally only used in cases where the work and the machinery are of a light description and where the cost of land outweighs the increased cost of buildings and the advantages of the single-storey shop.

It is advisable to arrange the position of the office buildings so that the entrance or exit to offices and works, both for persons and goods, may be controlled from one time and enquiry office. For small work where heavy cranes are not required, and where the type of machinery employed is small, the saw-tooth type of roof will be found most convenient; whilst for shops where the machines and the work are of a heavier description, and the spans consequently greater, a ridge roof is the best arrangement.

Figs. 1 and 2 show typical buildings comprising heavy machine and erecting shops, together with light machine and fitting shops.

The heights shown in the buildings are 30 feet for the erecting and heavy machine shops and 15 feet for the light machine and fitting shops. It will be noted that the roofs of all the bays are of the ridge type. The smaller bays of roofing are also of this description, since saw-tooth roofing should not generally speaking be of a greater span than 25 feet.

The widths of the bays depend on the machines employed and the character of the work to be carried out, and where these matters can be arranged to suit a bay of not more than 25 feet in width a roof of the saw-tooth type is undoubtedly the best. If the bays are of a greater width than 25 feet, the increased length of the glazing bars necessitates the use of a centre purlin and also increased strength in the rafter back.

The arrangement shown in figs. 1 and 2 is laid down on the supposition that the flow of work in the small machine bays will be parallel to the line of the larger bays, the machines and cranes where required being arranged in lines in this direction.

The roof principals are arranged at right angles to the length of the shop, so that the shafting, heating, and lighting pipes may be conveniently carried from them, and the span of the roof is accordingly 30 feet. Should, however, the character of the work to be carried out make it convenient to arrange the machines and cranes in the smaller bays at right angles to the length of the shop, the roof principals for the smaller bays will run in the contrary direction, and the span would be reduced to 25 feet, when a saw-tooth roof may be used with advantage. In tropical countries the use of saw-tooth roofing is almost compulsory as the rays of the sun are almost vertical.

Saw-tooth roofing where possible is usually arranged with the glazing facing north so as to prevent the direct glare of the sun through the glass. The principal advantage of the saw-tooth roof is that by its use a more evenly lighted and cooler shop is obtained.

The amount of glazing to be allowed for in a roof of the ridge type should be not less than about 50 per cent. of the area of covering, and in town districts with a smoky atmosphere this may be increased with advantage to 60 per cent. or 70 per cent.

The glass should be equally distributed on both sides of the roof, as by that means a more even illumination is obtained than when all the glass is placed on one side of the roof.

Another advantage of distributing the glazing is that the direct glare of the sun and consequent heating of the shops in summer is minimised.

FIG. 1.

ENGINEERING WORKSHOPS.

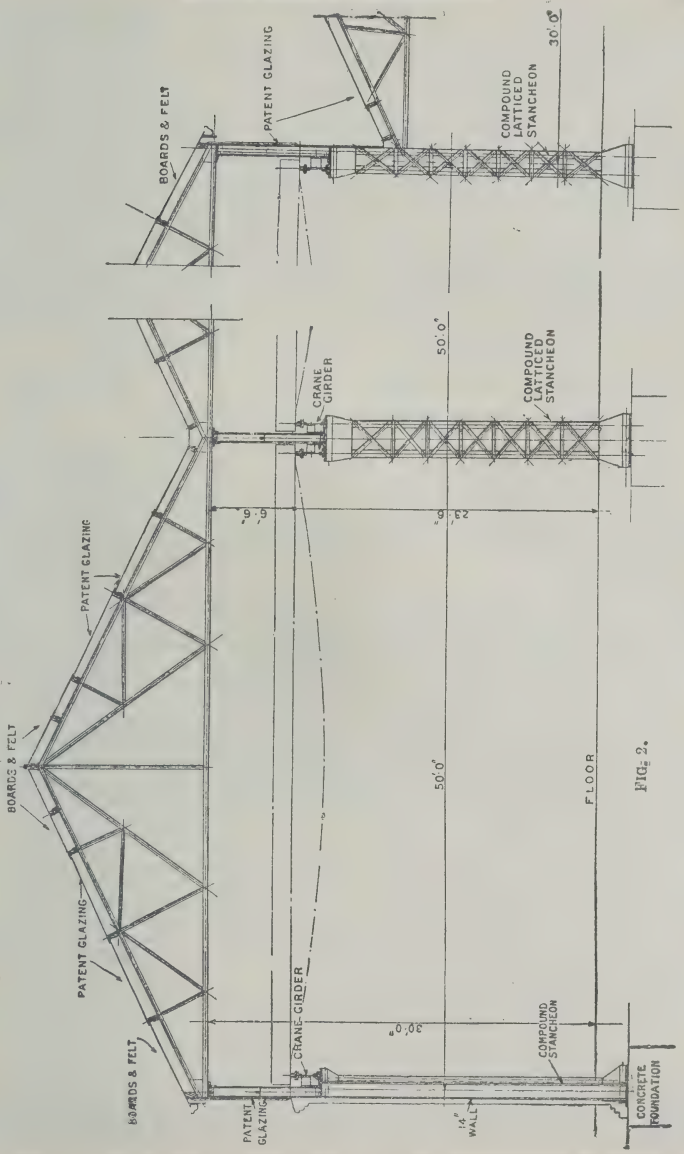

FIG. 2.

The roof covering in this country usually consists either of slates, asphalt felt, or corrugated iron.

For slates or corrugated iron the roof generally is given a rise of not less than quarter of the span, for if made of a flatter slope rain and snow are liable to blow in at the joints.

For felted roofs the roof may be practically flat if the joints are properly made with mastic, and it is only necessary to give a fall of one or two inches to the foot to allow for drainage.

Galvanised corrugated iron is usually only used in this country for buildings required for temporary purposes, and when used should be carefully painted before and after fixing, and afterwards properly maintained, as otherwise its life is only short.

Slating, when used, may be laid on battens nailed to spars, or to boarding nailed to the purlins. When laid on spars the slates should be pointed on the underside with hair mortar. When laid on boarding the boarding should be covered underneath the slates with sarking felt.

An alternative to natural slates is the use of asbestos slates. These are best laid either with the diagonal parallel to the slope of the roof, or in what is termed 'honeycomb' fashion. The point of the slate should be cut off, as it is otherwise liable to be broken by any one walking on the roof. It is necessary in all cases to see that proper lap is given to the slates, and this is especially the case where asbestos slating is used, as owing to its smooth surface the roof is more liable to leakage, where proper attention is not given to this.

An alternative to galvanised corrugated iron sheeting is the use of corrugated sheets of asbestos composition, which can be obtained up to 10 ft. in length and 27½ ins. in width.

Asphalt felt laid on thicknessed, grooved, and tongued boarding is cheaper than slating, and is not damaged like slating by men walking on the roof.

The use of felt of good quality is permitted by the building departments of most local authorities, although one or two treat it as not being sufficiently incombustible.

The felt is laid in mastic and nailed to the boarding, the joints being lapped about 4 ins. One thickness of stout felt will make a satisfactory job, if properly laid and if proper attention is given to maintenance, though the roof is generally covered with an extra thickness of a thinner quality of felt where a thoroughly good job is required. One advantage of the use of felt is that a considerable saving can be effected by forming the gutters in felt, instead of using cast iron gutters; this is especially the case in roofs where large valley gutters are required. A considerable amount of lead required for flashing at various parts of the roof can also be saved.

The only attention required to be given to felted roofs is a coat of varnish at intervals of about five years.

The roof glazing is best carried out with patent glazing, the alternatives to patent glazing being wood or tee steel glazing bars, the glass being puttied in.

The patent glazing is preferable, as with puttied bars the putty becomes defective and the glazing leaky, unless systematic attention and painting is given.

The best systems of patent glazing consist of a steel bar, to which is fixed a lead flashing, which is worked down on to the glass to form a weather-tight joint.

In most cases the glazing bar is sheathed all over in a lead casing, the ends of which are soldered up, thus obviating the necessity of painting. The bars should be galvanised before the sheathing is put on. Except in the case of vertical or steep-pitched glazing, as in the case of a saw-tooth roof, it is not advisable to joggle the glazing bar to form a lap in the glass. If this is done on a flat-pitched roof leakage is liable to occur, owing to capillary attraction between the two panes of glass. Where it is necessary to form a joint in the glazing on a roof of ordinary pitch, it is better to step the glazing bars.

The roof glazing is best carried out with wire wove glass, which holds together and does not drop if a pane is broken.

In a machine shop the number of cubic feet of air space is generally sufficiently large, in comparison with the number of men employed, to render extensive roof ventilation unnecessary, and sufficient ventilation may be provided by opening sashes in the glazing to a saw-tooth roof, or by ventilators at intervals along the ridge in the case of a roof of the ridge type.

The ventilators for a ridge roof to a machine shop are best provided with opening shutters so that the ventilation may be stopped in the winter or in driving rain or snow if required, or if preferred, exhaust ventilators can be used.

In the case of a foundry it is usual to provide ventilators with continuous louvres for the whole length of the shop. These are best made of wood with a rebated fillet screwed on the back to stop rain or snow from driving in as far as possible.

The roof principals are best formed in steel of angles, tees, and other rolled sections. A steel principal offers less obstruction to the light and harbours less dust than a timber principal, and can generally be designed at very little greater cost, if any.

For roofs of moderate span up to, say 50 feet, economical spacing may be taken as from 10 feet to 12 feet, which allows purlins of angle section to be employed. For roofs of larger spans it is frequently more economical to space the roof principals farther apart, and to use purlins of channel, zed, or rolled joist sections.

It is usual to arrange the roof so that the purlins are carried at the panel points of the truss, *i.e.*, at the intersection points of the rafter with the other members. If this is not done the strength of the rafter back must be increased to provide for the bending moment due to the load coming on to it from the purlin, in addition to the compression due to the internal stresses in the framing of the roof principal itself.

A factor of safety of 4, which is equivalent to a tensile stress of about 7 tons per square inch, is commonly used for buildings of a permanent description. In the case of buildings where a long life is not required this figure may be increased to 9 tons per square inch.

The stanchions and girders carrying the roof and gantries are now commonly made of steel of various sections in place of cast iron as in the older shops. A steel stanchion can usually be designed more economically than one of cast iron, is not so liable to damage from blows, and attachments can more easily be arranged for girders to carry shafting, jib cranes, etc.

Round cast-iron columns are sometimes used to carry the roofing of small spans for light machine shops, and light foundries where cranes are not required.

In cases where the crane loads and lengths of the stanchions permit, cheap and convenient forms are provided by the use of rolled steel joists of suitable section, with flat bars or steel channels riveted on to give additional flange area (figs. 3, 4, and 5). The section formed of a rolled steel joist and two channels is a very convenient one, and allows of the easy attachment of brackets, etc., in both directions.

FIG. 3.

FIG. 4.

FIG. 5.

Types of Compound Stanchions to carry Light Cranes or for Multiple Storey Buildings.

Where the shafting is carried from the crane girders, as is sometimes the case, the deflection and stiffness of the girders under load must be inquired into to ensure that the proper running of the shafting is not interfered with.

The economical spacing of the stanchions is determined by the total cost of the stanchions and foundations and the girders carried by them, but this must also in many cases be affected by the spacing of the machinery. In the small machine bays the tools will usually be arranged in long rows parallel to the lines of stanchions and the width of the bay will be a sum of the machine widths and alley ways. The spacing of the stanchions longitudinally will, however, not be affected by the machines, as these will usually be clear of the line of stanchions. For light work, bays arranged with the stanchions placed in squares of 20 feet will usually be suitable and economical in structural cost.

In the case of the large machine bays, the details of the machines will affect the centres of the stanchions longitudinally, as it will be frequently necessary to arrange for these to be placed partly between the stanchions. The width of the bay will be determined by the depth taken by the machines and the space required for assembling work and storing material. The spans and widths of bays shown will be generally convenient for a shop doing ordinary engineering work, but each case requires consideration and should be decided on its merits.

Provision must be made to carry the shafting on the stanchions for the larger bays, where the machines are not independently driven by motors. This is most conveniently arranged for by fixing four longitudinal channels braced together or two rolled steel joists at a convenient height.

The stanchions should be stayed transversely by knee bracing, or by lateral bracing, along the plane of the bottom member of the roof principals. In the case of very high buildings it may be necessary to use both methods.

The roof should also be braced diagonally along the planes of the rafters at the ends of the building, and in the case of very long buildings at intervals in addition.

The foundations for the stanchions and walls are best constructed of cement concrete, mixed six to one. No bedstones are necessary for the stanchions, which can be wedged up to the required level, and grouted with cement and sand in equal proportions. It is advisable to have one or two holes drilled in the stanchion base to vent same, and so allow of the escape of air when grouting. The walls are best constructed of brickwork, in hydraulic lime mortar, or may be framed and constructed of reinforced concrete, about 3 ins. to 4 ins. in thickness.

By the use of special metal lathings, which can be plastered on both sides with cement mortar, it is possible to obtain a weatherproof material with a thickness of 2 ins. If this material is used, a waterproofing medium should be added, in mixing, to the mortar for the outer covering.

This latter method of construction is specially applicable to the filling in to the sides of the main bay, above the roof of the small machine shop, and to the ends of ventilators. It may be also used for a roof covering, where it is necessary that no inflammable material should be used.

Where it is desirable to erect a building with more than one floor, or where galleries are required in a machine shop, these are best constructed with a main framework of steel. The stanchions should be composed of rolled steel joists, or of compound sections, as shown in figs. 9 and

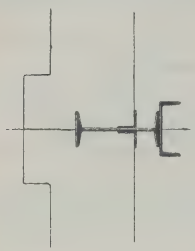

FIG. 6.

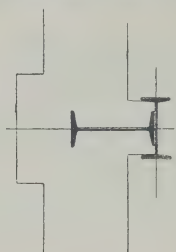

FIG. 7.

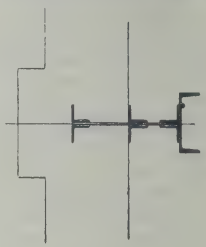

FIG. 8.

Types of Wall Stanchions to carry Cranes.

10, the main floor girders being rolled steel joists or plate girders, as required by the loads coming upon the floor. The depths of the main joists and girders should not be less, if possible, than $\frac{1}{12}$ of the span.

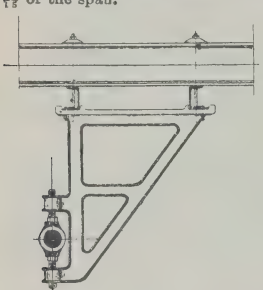

FIG. 9.

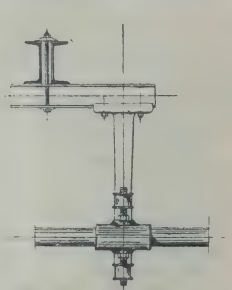

FIG. 10.

Detail Connections for carrying Shafting.

The use of a steel frame construction is especially desirable in a building of more than one storey, as the lower floors are dependent for light on the windows, which are placed in the side walls. If steel framing is used, the covering material of brickwork or concrete can be reduced to a minimum, and the window area is correspondingly large.

Floors.

Floors are now generally made of concrete, either with or without a covering of timber.

When the wearing surface is of concrete it should be finished with granite sand and cement, in equal proportions for the thickness of one inch. Concrete is not so suitable as wood for the wearing surface of a floor. It is always impossible to ensure freedom from cracks in concrete over large areas, it is tiring to walk on, is dusty, and liable to damage tools and fragile articles dropped upon it.

If a wood floor is used it is usually laid on a foundation of cement concrete, usually from 4 ins. to 6 ins. in thickness, this being a variable dimension depending on the loads to be put upon the floor, and on the nature of the subsoil.

For floors where the work is of a heavy description the best surface is one of wood blocks 4 ins. deep, which may be formed by sawing off 3-inch deals to lengths. To prevent damp from rising through the concrete the upper surface of the foundation should receive a coat of coal tar pitch about $\frac{1}{4}$ inch thick applied hot, and the blocks should be dipped in the hot coal tar and bedded whilst the pitch is hot, any open joints being afterwards run in with pitch. Where the work is of a lighter character, the most satisfactory wearing surface is grooved and tongued maple planking, nailed either to 4-inch by 3-inch battens laid in the concrete or to planks laid transversely.

The battens should be creosoted, or dipped in 'Jodelite' or 'Sideroleum,' or some similar wood preservative, and the planking laid in hot tar. It is very important that the whole surface of the floor should be thoroughly tarred before the wood blocks or planking are laid, and that any wood blocks or pegs used for levelling purposes should be removed. Where the loads are very light and the foundation good, tar concrete may be substituted for the cement concrete, the upper surface being tarred as before.

The supported floors of a multi-storey building, or of galleries, are usually constructed of concrete where a fire-resisting floor is required, or of timber in other cases. Where a concrete floor is used it may be constructed of reinforced concrete, or preferably of rolled steel joists and concrete, as the more or less concentrated loads from machines and materials coming on the floor can be more easily arranged for.

In this case the floor can be constructed of small steel joists from 4 ins. to 7 ins. deep, according to the span and load, spaced about 2 feet apart, and finished with a flat ceiling. If the concrete is arched or recessed between the joists, hangers can be easily attached by hook bolts to carry countershafting. Another method where the loads are considerable is to use joists of heavier section, and to form an arched floor of concrete between these.

The upper surface of the floor can be finished with wood planking, as previously described. If the floor is constructed of timber, wood joists bedded on the steel main girders can be used, with wood planking laid on top. It is well, if this form of floor is used, to finish the floor with boards from 1 in. to 1½ in. in thickness, nailed transversely to the planking. Both the planking and the boarding should be thicknessed and laid with grooved and tongued joints.

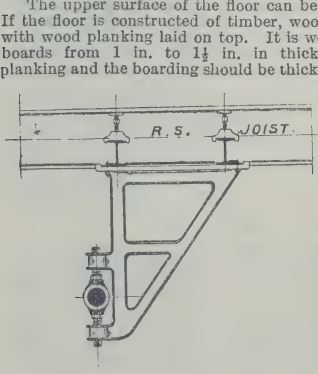

FIG. 11. Detail Connections for carrying Shafting. FIG. 12.

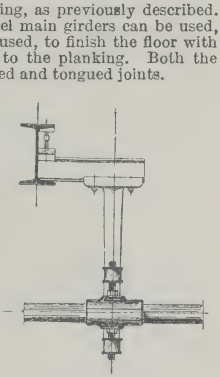

Window sashes are best formed of steel, which if properly painted at intervals is as durable as wood, offers less obstruction to the light, especially in windows of large size, and can be obtained at the same or less cost. The heads to windows may be brick arches, but are preferably formed of concrete, reinforced with small rolled joists or tees.

The position of the sanitary conveniences should be arranged so that undue time is not wasted by a long journey from the shop and back. The minimum accommodation is fixed by the Factory Acts, and the Bye-laws of the local authorities. A regulation of the Factory Acts which is strictly enforced by most local authorities, requires the conveniences to be cut off from the main building by a free air space, and this is undoubtedly desirable from a sanitary point of view.

The foreman of a shop should have a desk and office in that shop. The position should be arranged so as to give him a convenient oversight over the whole of the men employed.

The office may consist of a portion of the shop railed off or of a small wood building glazed all round and raised above the general floor level so as to overlook the shop.

Dry grinding machinery is always to be exhausted by a fan.

Smith work is best done in a separate building. Light smiths' fires are supplied with exhausting fans to clear the smoke.

Wood-working shops may be fitted with exhausters to remove all waste, which is best delivered to the boiler house and destroyed.

As no work can be done cheaply without thorough gauging arrangements, the modern method is to use the limit gauge system, for which purpose every works must have a full set of accurate high-class gauges to be used with special care in testing the working gauges, which may be made of cheaper material, and rejected as wear places them out of the limit of accuracy required.

Finished parts should be inspected as made, and finished machines when ready for shipment.

The tool room is an essential department in a modern workshop. In it are kept all tools and gauges required, and every tool given out for use should have a check in its place in the tool room. Fixtures, belts, and other requisites for different tools should have a place on a shop stand, which may be simply a shelf or two of plate iron, supported by pipe framing. No accumulations must ever be allowed on the floors and in corners. Conical pointed buckets provided for dirty waste cannot be left standing about, but must always be in place in their ring stands.

Provision must be made for the prompt removal of all chips, especially if greasy. Where automatic machinery is employed, oil is pumped over the work by a pump in the machine itself. In some shops oil is supplied in pipes, and returns to the pumps through pipes by way of filters. Machines very freely supplied with oil for the tools should be stood on lead-protected floors to prevent oil soakage. Greasy chips can be purified of oil in a centrifugal machine.

In a large works a tool room in each room or on each floor may be required; but no more than actually needful should be provided. Preferably rooms should be as large and as few as possible. The tool room fully carried out includes much more than mere storing and providing tools; its duty is to lay out systems of doing work, and to collaborate with the drawing office in regard to materials and stores. It is in a sense not merely a part of the works: it is also a part of the managerial department.

The drawing office also should be more than a mere room for drawing. It is, or should be, the very centre of management, for from it should emanate design, orders for materials, and the intellectual work of the whole establishment, so that design may be kept in touch with materials, market prices, etc.

Where tools are belt driven, it is usual to employ a countershaft between line shaft and tool, but if the line shaft runs at 250 r.p.m., as a modern shaft may well do, the countershaft may be omitted; there would then be a fast-and-loose pulley on the machines themselves, and no cone pulleys, their place being taken by the all-gear headstock in the lathe.

Heavy lathes may be driven from built-in motors set across the bed, and driving through chains a worm shaft with a right and left worm driving worm wheels on each side of the face plate wheel, and pinions in the worm shafts driving this wheel.

The introduction of high-speed steel, with its great capacity for removal of metal and its large absorption of power, has completely changed conditions. In the lathe the tendency is to abandon the stepped belt cone and employ a single belt pulley, only driven, it may be, directly off the line shaft, speed variations being obtained by gearing. Motors are still frequently belted to a machine, but the tendency is towards making the motor an integral part of the machine it drives. Small tools are more economically group driven from a shaft and a single motor. Whether tools shall be driven in groups or by a single motor to each tool can only definitely be decided by the actual conditions of the case. Where every machine has its own motor the aggregate power of all the motors will be two or three times that of the current generating dynamo.

The application of electrical methods has tended to advance gas and compressed air and mechanical hammers to displace steam hammers; but for larger work the steam hammer is still imperative, being superior to any other hammer. But for the very largest work of forging, the hydraulic press now does the best work, and steam hammers are not made equal to dealing with the largest work now undertaken.

In place of hooks for lifting, shop cranes are sometimes fitted with electro-magnets for lifting plates or such articles as can be thus easily held. By this means time is economised, for there is no use for slings, and the load can be put down by the lift man without help from labourers to detach, simply by the turn of a switch.

For much work that is too heavy for easy movement, the machine tools are carried to the work. In this system the floor is of heavy cast-iron girder plates grooved like the platen of a planing machine. Work is laid upon this floor, and machine tools are bolted to the floor, and operate on the work. This is rendered possible by a system of electric driving, the motors being part of the machine. Machine tools may be attached to the work, and the designer should take this into consideration in his design, since by slight modifications the work may be made so as to facilitate such fixing of the tools.

FLOOR SPACE FOR MACHINE TOOLS.

Size.	Machine.	Greatest No. of Machines per 1,000 sq. ft.
12 ins. to 20 ins.	engine lathes, faced same way	20
12 ins. to 20 ins.	engine lathes, back to back	24
22 ins. to 24 ins.	planers, heads and tails	10
22 ins. to 24 ins.	planers, faced same way	9
28 ins. to 30 ins.	planers, faced same way	5
14 ins.	multi-spindle drills	40
16 ins. to 20 ins.	upright drills	36
26 ins. to 30 ins.	upright drills	12
Small milling machines		36
Ordinary milling machines and automatic screw machines		20
Hand screw machines and plain and universal grinders		15
Polishing machines		24

The above areas are exclusive of main passage-ways, and if it is decided to run a 6 ft., 8 ft., or 10 ft. passage the entire length of building this area must be added.

Every tool in a workshop should be drawn in outline as regards its leading dimensions, and the drawing pasted on a suitable board together with the overall dimensions of the work it will take, the speeds, feeds, and other information for the drawing office.

The drawing office should be the repository of all information as to stock material; it should really include the stores and purchase department, and work in progress in the shop, and during erection should be visited by the draughtsmen chiefly concerned, so that needless costs and charges in manufacture and erection may be avoided.

Concrete Floors.

To deaden the noise from trucks rumbling over a concrete floor, use a heavy tar paper pasted to the floor by paint. The floor to be protected is first given one coating of grey cement paint. On the following day, when the paint is thoroughly dry, a second coat is applied. At the same time one side of a five-ply tar paper is painted; and when both paper and floor are still wet the paper is carefully laid, wet side down, on the floor and rolled with either a roller or wide-tired truck until all signs of air-pockets beneath the paper disappear. The surface improves with age, and very effectively reduces noise at a low cost.—*Contract Record.*

Oil stains on concrete floors may be removed by using a mixture of 1 lb. of oxalic acid in 3 gallons of water, with enough wheat flour added to make a paste that can be applied with a brush. Allow the application to remain for two days, and then remove it with clean water and a scrubbing brush. A second application may be necessary in stubborn cases.—*Building News.*

To remedy dusty concrete floors, a surface treatment of some kind should be applied to remove the surface skin which does not exceed $\frac{1}{32}$ in., or properly to treat it. One way is to grind the surface by hand or power as a terrazzo floor is polished. Other methods are to apply liquid coatings of various kinds. One of the most satisfactory treatments is with boiled linseed oil thinned with petrol to such a consistency that it will penetrate the pores of the surface. If one coat does not cure the trouble generally two will. A second method is to clean the surface thoroughly and then apply a coat of silicate of soda or water glass, 40 deg. Baumé, diluted one part to six of water, to seal the surface. Then wash off the excess which opens out the pores again and apply a second coat.

See also p. 393.

For making slippery iron floor plates reasonably safe under ordinary shop conditions, mix a small quantity of powdered sal ammoniac thoroughly with a large quantity of fine sand. Sprinkle the mixture over the floor so that all parts are covered, and damp the surface with a watering can and let it lie over a week-end, or even overnight, then sweep the sand up. The rust coating formed by the treatment will be found to last for several weeks, after which the process must be repeated.—*Ironmonger.*

Care of Factory Windows.

A number of tests of the reduction of daylight in factories has been made by the engineers of the Detroit Steel Products Company, Michigan. It was found that with vertical glass the transmission of light through the windows decreased rapidly during the first 20 days after cleaning, from a normal transmission of 80 per cent. for clean glass to 65 per cent. The decrease continued to 34 per cent. at the end of 120 days. Sloping glass collected more dirt. At slopes of 15°, 30°, and 45° the transmission of light decreased from 80 per cent. to 60, 55, and 50 per cent. respectively, in the first 20 days, and to 25, 19, and 16 per cent. at the end of 120 days. Whilst at first sloping windows on a roof admit more light than an equal area on the vertical, this advantage is lost at the end of six months. Owing to wind and rain about one-fourth of the dirt is found on the outer surface and three-fourths on the inner. Factory windows should therefore be washed more often on the inside than on the outside. The autumn, not the spring, is the right time for washing, as during the dark winter months the windows will have been recently cleaned. So far as collection of dirt is concerned there is not much difference between various types of glass, but ribbed and figured glasses are much harder to clean. The roughened side of the glass should be outside, as less dirt collects on that side.

(*W. C. Randall and A. J. Martin*, '*American Ill. Eng. Soc.*,' vol. 22, 1927, pp. 239–253.)

Electric Power Driving.

Where many small machines are placed near together and driven more or less intermittently, one small line shaft and one motor will drive all the little machines, and the motor will be of far less cost and power than the aggregate of motors if applied one to each machine. But for large machines, single motors to each machine are a decided economy.—*C. H. Benjamin.*

The Use of High-Pressure Gas in Works.

A satisfactory arrangement is to have a shop supplied with gas at 200 ins. pressure, to be reduced at the various furnaces, etc., by means of governors or valves, to the predetermined pressure corresponding with the temperature it is desired to maintain in each furnace. Pressures suitable for typical work are as follows:—For melting tin or solder a pressure of 65 ins.; for small furnaces for hardening, etc., the same pressure may be used; for blueing steel, from 65 ins. to 80 ins., the flames playing horizontally under the lime-tray set in a brick frame; for the lead-pot for tempering steel the pressure should be 150 ins.; while for melting metals at from 2000° to 2000° F. it should be 200 ins. Soldering-irons may be heated with gas at 65 ins.; two burners, consuming 6 ft. of gas per hour, and playing direct on to the irons, being sufficient to keep a workman going without delays. For lighting, gas at 65 ins. may be used.

With gas at 2*s.* per 1,000 and coal at 20*s.* per ton there is little to choose between gas and coal firing as regards cost. As regards cleanliness, uniformity, etc., the advantages are, however, in favour of gas, and in many cases with properly-designed furnaces it is greatly superior to coal, not only from the point of view of cost, but from convenience and ease of manipulation. A properly-designed gas-furnace will enable the time of preparation from the cold to be greatly shortened.—*A. W. Onslow.*

WORKSHOP PRACTICE.

Limits and Limit Gauges.

There are four usual 'fits' in practical mechanics, namely—

The *force* fit, which requires a screw, a hydraulic press, or the use of heat on one piece to get the fits together. The *drive* fit, which can be done by a hammer. The *push* fit, which can be pushed together by hand, and may even be revolved slowly, but would heat and seize if run for any time; and the *running* fit, which will run indefinitely if lubricated, and varies with the class of work. Running fits may be divided into several classes, and are classed in three divisions by the Newall Engineering Co.

The provision of a separate external limit gauge for each and every diameter used—and for each variation in the quality of fit required on such diameter—would entail in most cases an expenditure so heavy as to practically prohibit the installation of a full equipment; yet in modern commercial production efficient means of gauging work are imperative, and, to overcome the necessity for the multiplicity of external limit gauges required, an adjustable type was specially designed and introduced by the Newall Engineering Co. These being adjustable, they are not affected by wear as are all solid gauges.

The gauge has two fixed anvils on one jaw and two movable anvils (adjusting screws) on the other jaw, forming two pairs of measuring faces, the front pair being the 'go' and the back pair the 'not go' points; the adjusting screws are securely locked in position by means of cotters and nuts of special design. Each gauge, by the length of travel of its adjusting screws, covers a range of sizes, and can be easily and quickly set up to such diameter and limits within its range as may be wanted.

There are two methods of setting up or adjusting the measuring points. The first is by means of limit reference bars ground to the 'high' and 'low' limits for the different allowances prescribed in standard tables. The other method is with standard reference bars and 'setting dials'; the adjusting screws of the external limit gauges have taper holes in their inner ends, and the dials are provided with taper shanks which fit into these holes. The 'go' and 'not go' points of the gauge are set to a standard reference bar (or other reliable standard) of the nominal size required; the adjusting screws are then locked and the dial and index inserted at zero. The screw carrying the dial is released and can be adjusted to the desired allowance, either above or below 'standard,' by rotating the screw in the plus or minus direction, as shown by the arrows on the index. This screw is then locked, the dial and index transposed, and the process repeated with the other screw. For English sizes the dials are divided to read by 0·00025 in., and for metric sizes by 0·01 mm. One pair will serve for all gauges up to 6 ins., or 150 mm.; gauges over these sizes require a larger pair.

Definitions as given by the British Engineering Standards Association:—*Tolerance*—a difference in dimensions prescribed in order to tolerate unavoidable imperfections of workmanship. *Allowance*—a difference in dimensions prescribed in order to allow of various qualities of fit.

British Standard Limits and Fits for Engineering.*

(No. 164—1924.)

(*Abstract.*)

In 1906, Report No. 27 on British Standard systems for limit gauges was issued. In this Report the shaft was recommended as the constant member, but the recommendation was not generally adopted by the engineering industry. In 1917, therefore, a Committee was appointed to revise the Report, and to consider the whole question of limits for cylindrical work for the engineering industry in general. The present Report is the work of that Committee and is in substitution of Report 27—1906.

The Committee has unanimously decided to reverse the previous decision and to recommend the adoption of the hole as the constant member.

This is generally referred to as the 'hole basis' when speaking of a system of limits, and the principal table of standards will give the tolerances appropriate to holes of different sizes and different grades of workmanship, so that all holes of the same nominal size and same specified grade will be interchangeable.

* By permission of the British Engineering Standards Association.

TABLE I.—BRITISH STANDARD LIMITS AND FITS FOR ENGINEERING. UNILATERAL, BILATERAL, AND OVERSIZE HOLES. (British System—Inches.)

All Dimensions except Nominal Sizes are expressed in thousandths of an inch.

1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26
Size Multiplier.	Nominal Sizes.	UNILATERAL HOLES. (In which the Low Limit of the Hole is Nominal Size.)								BILATERAL HOLES. (In which the Nominal Size of the Hole lies between the High and Low Limits.)								OVERSIZE HOLES. (In which the Low Limit of the Hole is larger than the Nominal Size.)						Non-Mating Holes and Shafts.

+ = Clearance; − = Interference; the upper figures in each square represent the Minimum, the lower figures the Maximum, Limit of Fit.

Two systems are in common use. In the unilateral system the tolerance is in one direction only from the nominal size and is usually positive: that is to say, every hole in the unilateral system is of the nominal size or larger. In the bilateral system the tolerance extends in both directions (but not always in equal amounts) from the nominal size: that is to say, holes in the bilateral system may be smaller or larger than the nominal size.

The Committee has unanimously agreed to recommend the use of the unilateral system as applied to cylindrical mating surfaces in cases where it does not conflict with predominating present practice.

In deciding on the system of gauging and the amount of the tolerances to be employed, it is important to distinguish between mating surfaces, in which the inter-relation between the surfaces in contact is the guiding feature, and non-mating surfaces in which only one surface has to be considered. The tables in the present report refer primarily to mating surfaces.

2. Table I gives both unilateral and bilateral limits of tolerance for holes. In the unilateral system, the nominal size is the low limit of the hole; in the bilateral system, the nominal size lies between the high and low limits of the hole.

3. Table II gives the recommended limits of tolerance for a standard series of graduated shafts suitable for pairing with either the unilateral or bilateral holes. Table III shows the numerical values of the limits of fit resulting from the assembly of any one of the standard shafts in a particular unilateral hole and a particular bilateral hole. The numerical values of the limits of fit resulting from the assembly of the standard shafts in any of the other holes specified in the tables can be arrived at by simple arithmetical calculation.

4. The effect of transferring any standard shaft from a bilateral hole to a unilateral hole tends either to increase the clearance or decrease the interference—i.e. it makes the fit easier.

6. Table I provides four standard grades of workmanship for holes, in which B (unilateral) and K (bilateral) holes represent the most accurate grade, while U (unilateral) and X (bilateral) holes represent those most commonly employed. Unilateral holes V, W, and bilateral holes Y, Z, have larger tolerances.

7. Table I also provides for the use of three holes A, G, H, each with two positive limits of tolerance. These are called oversize holes. They are common to both the unilateral and bilateral systems, and are included in the table to meet exceptional conditions.

The limit values in the tables are found by multiplying together the '*size multiplier*' '*m*' and the '*range factor*' '*r*,' odd half-ten-thousandths being eliminated by subtracting such odd amounts from the products in which they occur, negative products thus becoming more negative.

Example:

To find the limits for a $2\frac{1}{4}$ in. U hole.

The value of '*m*' corresponding with $2\frac{1}{4}$ ins. is 8; see Table I.

The value of '*r*' for the High Limit of U = 2 (in ten-thousandths of an inch[2]).

The value of '*r*' for the Low Limit of U = 0.

Hence, required limits are + 0·0016 in. and + 0.

Tables with metric values are also given in the Report.

Limit Arms for Micrometers.

A ready means of converting an ordinary micrometer to a limit gauge having a tolerance of from 0·0001 to 0·022 in. with variations of 0·0001 in. is provided by a pair of arms (fig. 13) manufactured by Messrs. Accles & Pollock, Oldbury, Birmingham. The micrometer having first been set to the low limit required, the pair of arms are cramped compass-friction-tight on to the micrometer barrel, the short arm just clearing the figures at the bevelled end. The short arm is now adjusted from its cramp end, so that it strikes the back of the frame at the

low limit. The screws are then tightened. The long arm is similarly adjusted so that it strikes the front of the frame at the high limit. When the change to new limits is greater than one

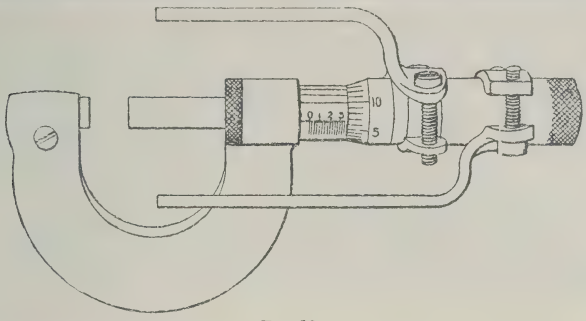

FIG. 13.

revolution of the thimble, the screws are slackened, and both arms brought to the top; the procedure is then as before. The ordinary use of the micrometer is not interfered with.
(' *Machinery.*')

INDICATOR FOR WIRE GAUGE.

A simply made indicator to enclose the notch of a wire gauge that is in use, and save time and trouble when making repeated gaugings, or searching amongst stock or scrap, can be made as

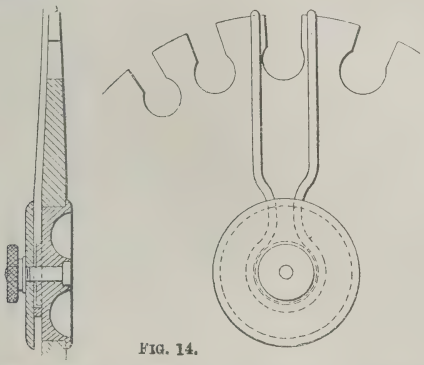

FIG. 14.

shown by fig. 14. The principle is to use springy wire, which may be altered to come just outside the edges of each opening. After holding it at this setting, clamping is done by tightening the knurled nut, which draws the large washer down on the wire and binds it. (' *Machinery.*')

Cost of Unnecessary Accuracy.

Very small limits are often indicated on drawings when it is not only extremely difficult to machine to them, but also when such accuracy is not only unnecessary but causes time and money to be wasted in the drawing office as well as by the man in the shop.

The following examples emphasize the need for sound judgment in deciding when close limits are and are not required.

A firm manufacturing small tools received an inquiry for a metal slitting cutter of the circular disc type. Tolerances were specified to $\pm$ 0·00005 in. The tool manufacturer quoted 20*l.* a piece for these cutters. On the customer replying that the price was excessive, the manufacturer asked him to specify the purpose for which the tools were to be used, and requested that he be

permitted to use his own judgment as to the accuracy required. The result was that perfectly satisfactory cutters were made with tolerances of ± 0·00025 in., which reduced the cost per cutter to 15*s.*

In another case a blue-print was submitted to a manufacturer calling for a screw over 20 ft. long, 3½ ins. in diameter, having four Acme threads to the inch. The tolerance on the pitch diameter and lead per inch was given as ± 0·0001 in. A quotation of over 2,000*l.* was made for the screw. It was estimated that, on account of the size of the screw and the difficulty of handling it, the setting up for making dependable measurements of a pitch diameter and lead error to within the limits required, would have cost about 4*l.* per measurement. In this case there was absolutely no need for accuracy. If there had been a $\frac{1}{10}$-in. tolerance on the diameter of the screw either way it would have made no difference in its application because the nut was to be fitted to the screw by the manufacturer who made the screw, and so long as the two fitted together, there was no question of interchangeability, because only one screw and nut were to be made. Finally, more reasonable tolerances were set on this screw, and it was made for 63*l.* instead of thirty or forty times that amount.

Frequently draughtsmen dimension fillets in decimals, indicating that great accuracy is required. The tool maker generally knows that no accuracy is really wanted, but if he were to follow the drawing exactly he would make the tools with such unnecessary accuracy as to increase their cost several times. If a fillet is marked $\frac{3}{16}$, it is clear that no great accuracy is required, but when it is dimensioned 0·1875 it would appear that an accuracy to the fourth decimal place is wanted.

(*'Machinery,'* August 19, 1926.)

Estimating Cost of Steel Bars.

Locate on axis OA (fig. 15) the position which represents the price in shillings per cwt. at which the particular steel can be bought. From that point travel to the right, horizontally, until the diagonal which represents the diameter of bar required is reached. From that point pass vertically down to axis OB and read off the price per foot for bar of that diameter in the material required.

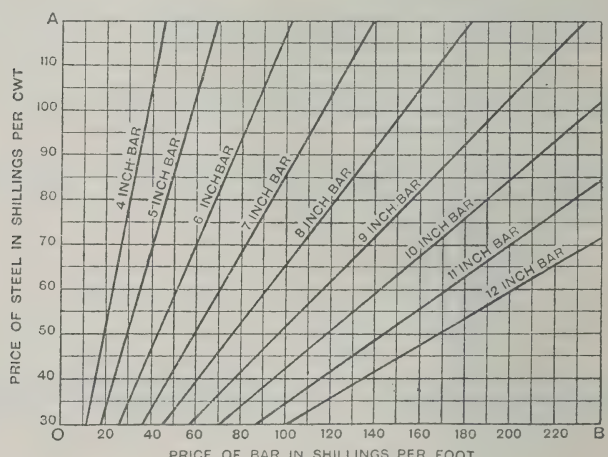

FIG. 15.

The chart covers steels from common mild steel to high grade nickel-chrome steels, and it can be used for determining the value of forgings if the price of plain forgings per cwt. is known.

FLOUR MILLING—COTTON MILLS—OIL MILLS—CANE-SUGAR MILLS AND MACHINERY

(pp. 783-797)

SECTION XVII

FLOUR MILLING — COTTON MILLS — OIL MILLS — CANE-SUGAR MILLS AND MACHINERY.

FLOUR MILLING.

(Contributed by E. R. & F. Turner, Ltd., Engineers, Ipswich.)

Fifty years ago the reducing of wheat to flour was done almost entirely by means of stones; now it is done by chilled iron rolls, except in a few countries where stones are still retained.

Stones are still used in England and elsewhere for making 'stone' flour, whole meal, farmers' grist, etc. They are usually from 36 to 48 ins. in diameter, top stone the runner, driven by gearing from a horizontal layshaft; speed about 150 revs. per minute; horse-power required from 8 to 12 b.h.p., but largely dependent on the condition of the grain and the sharpness of the dress in the stones.

ROLLER SYSTEM.

The very white, high-class flour of the present day is obtained by means of a very elaborate system. Every mill of any size is fitted with:—

1. Intake plant. 2. Wheat-cleaning plant. 3. Milling plant.

The intake plant for getting the wheat from trucks or barges into the mill may be either pneumatic (suction) or elevator, and is arranged so that the wheat may be deposited into any one of the storage bins or silos provided for the purpose.

The cleaning plant consists of scourers, aspirators, brush machines, etc., and also includes a plant for washing and drying such wheats as require this treatment.

The milling plant consists of roller mills, purifiers, and dressing machines connected by spouts, elevators, and conveyors. The actual roll contact surface is usually about 100 ins. per sack of 280 lbs. of flour per hour, which is divided up into approximately 40 ins. on the break rolls and 60 on the reductions. The break rolls are fluted from about 12 to 26 per inch, for opening the wheat berry, releasing the kernel and cleaning the bran, which is separated by means of sieves; the reduction rolls are smooth or very finely fluted or scratched, and reduce the kernel into fine flour, which passes into sifting machines and is dressed through fine silk. Sifting machines may be either of the reel type with internal beaters, commonly called 'centrifugals,' or the flat sieve, called 'plansifters,' both types being covered with silk containing from 100 to 150 threads per lineal inch for dressing out the finest flours, or coarser if required.

The semolina and middlings released by the break rolls are passed through purifiers in which strong currents of air pass through them, eliminating fine branny particles and other impurities before they are passed on to the reduction rolls.

Exhaust fans are connected to all machines for drawing away the hot air which is generated by the rolls and other frictional surfaces.

One sack of flour (280 lbs.) is made from 400 lbs. of wheat.

Angles of spouts for wheat should be not less than 25 degrees, and for flour and bran not less than 55 degrees.

Speed of elevators for wheat 300 to 350 feet per minute.
" " flour 180 feet per minute.
" " other mill stock 220 feet per minute.
Speed of spiral conveyors 150 feet per minute.
" band conveyors for wheat 9 feet per second.
" " " light stock 3 feet per second.
" break rolls 900 feet per minute.
" reduction rolls 630 feet per minute.

Power required about 10 to 12 b.h.p. per sack of flour per hour.

See also 'Modern Flour Milling Machinery,' by Lt.-Col. F. W. Turner (Paper read at Summer Meeting of the Institution of Mechanical Engineers, at Ipswich, June 15th, 1926). *Proceedings of the Institution of Mechanical Engineers*, No. 4, 1926, and *Engineering*, July 2nd, 1926.

COTTON MILLS.

(*BLACKBURN DISTRICT. YATES & THOM, ENGINEERS.*)

For 90,000 mule spindles and preparation.
Main building, 281 feet by 130 feet; 4 floors; 3 spinning rooms; 1 card room.
74 self-acting mules. Indicated horse-power, 1,380. Boiler-pressure, 160 lbs.
Engines.—Triple-expansion double-tandem condensing; one high-pressure cylinder, one intermediate cylinder, two low-pressure cylinders :—

Diameter of high-pressure cylinder, 21 inches; ratio, 1·0; stroke, 5 feet 6 inches.
Diameter of intermediate-pressure cylinder, 34½ inches; ratio, 2·7; speed, 60 per minute.
Diameter of each low-pressure cylinder, 39 inches; ratio, 6·9; piston speed, 660 feet per minute.

Rope pulley 30 feet diameter, grooved for 32 ropes 1⅝ inch diameter.
Velocity of ropes, 5,654 feet per minute.
Boilers.—Steel. 4 Lancashire type (one being spare); length, 30 feet; diameter, 8 feet. Furnaces, diameter 40 inches; working pressure, 160 lbs.
Economiser.—Green's type, from 278 to 384 pipes.
Mill Shafting.—Card shaft, 185 revolutions; 3⅜ inches to 2½ inches diameter.
9 drawing frames, 9 slubbing frames, 16 intermediate frames, and 44 roving frames of 176 spindles.
Roving shaft, 270 revolutions, 3½ inches to 2½ inches diameter.
Drawing, intermediate, and slubbing shaft, 225 revolutions, 3⅝ inches to 2½ inches diameter; drives also 27 cards.
Spinning-room shafts, 4¼ inches to 2¾ inches diameter.

For 71,000 ring spindles and preparation.
Boilers.—Four Lancashire, 30 feet by 8 feet, 160 lbs. per square inch, with Green's economiser of 384 pipes.
Engine.—Horizontal cross compound, 1,700 i.h.p. at 66 r.p.m.
Cylinders, 30 inches and 60 inches diameter by 5 feet stroke.
Jet condenser 50 cubic feet capacity. Two air pumps, each 31 inches diameter by 17-inch stroke at 66 r.p.m.
Flywheel, 24 feet diameter, 57 tons, 43 ropes 1⅜ inch diameter.
Rope-speed, 4,970 feet per minute; i.h.p. per rope, 39·5.
Piston speed, 660 feet per minute; air-pump speed, 187 feet per minute.
Cylinder ratio, nominal, 4 to 1; m.e.p., 30 lbs. per square inch.
Machinery.—Includes 15 opening and scutching machines, 132 cards, 18 drawing frames, 11 slubbing frames, 16 winding frames, 22 intermediate frames, 48 roving frames, 164 ring frames of 432 spindles each, 22 beaming machines, 6 warping mills, 100 reels, and 4 bundling presses.

The following are plants completed at Royton, Rochdale, Leigh, and Atherton, by Messrs. Yates & Thom, just before the war :—

ROYTON.

For 117,584 mule spindles, 10's to 24's counts.
Horizontal cross compound engine cylinders, 28 inches and 58 inches diameter, 5 feet stroke, 1,600 i.h.p.; 65 revolutions per minute.
Four boilers, 30 feet long, 8 feet 6 inches diameter, 180 lbs. pressure.
Economiser, with 480 pipes.
Fly rope pulley, 24 feet diameter; 40 1⅝-inch ropes.

For 132,000 mule spindles, 10's to 42's counts.
Horizontal cross compound engine cylinders, 28 inches and 58 inches diameter, 5 feet stroke, 1,600 i.h.p. ; 65 revolutions per minute.
Four boilers, 30 feet long, 8 feet 6 inches diameter, 180 lbs. pressure.
Superheaters.
Fly rope pulley, 24 feet diameter ; 40 1⅝-inch ropes.

ROCHDALE.

For 41,000 mule and ring spindles, 3's to 12's counts.
Horizontal cross compound engine cylinders, 19 inches and 40 inches diameter, 4 feet stroke, 600 i.h.p. ; 70 revolutions per minute.
Two boilers, 32 feet long, 8 feet 6 inches diameter, 180 lbs. pressure.
Economiser, with 192 pipes.
Fly rope pulley, 22 feet diameter ; 21 1⅝-inch ropes

LEIGH.

For 94,560 mule spindles, 40's to 80's counts.
Horizontal cross compound engine cylinders, 23 inches and 50 inches diameter, 5 feet stroke, 1,200 i.h.p. ; 65 revolutions per minute.
Three boilers, 30 feet long, 8 feet 6 inches diameter, 180 lbs. pressure.
Economiser, with 288 pipes.
Fly rope pulley, 24 feet diameter ; 33 1⅝-inch ropes.

For 85,000 mule spindles, 40's to 90's counts.
Horizontal cross compound engine cylinders, 23 inches to 50 inches diameter, 5 feet stroke, 1,200 i.h.p. ; 65 revolutions per minute.
Three boilers, 30 feet long, 9 feet diameter, 180 lbs. pressure.
Economiser, with 288 pipes.
Superheaters.
Fly rope pulley, 24 feet diameter ; 33 1⅝-inch ropes.

ATHERTON.

For 100,000 mule spindles, 60's to 90's counts.
Horizontal cross compound engine cylinders, 28 inches and 56 inches diameter, 5 feet stroke, 1,500 i.h.p. ; 66 revolutions per minute.
Four boilers, 30 feet long, 8 feet diameter ; 165 lbs. pressure.
Economiser, 384 pipes.
Fly rope pulley, 24 feet diameter ; 37 1¾-inch ropes.

(*STOCKPORT DISTRICT. J. & E. WOOD, ENGINEERS, BOLTON.*)

For 53,000 ring spindles and preparation.
Main building, 249 feet by 95 feet ; 5 floors and basement.
140 ring spinning frames of 376 to 396 spindles each, spinning 16's to 40's yarn.
Indicated horse-power, 1,500. Boiler-pressure, 165 lbs.
Engines.—Triple-expansion condensing double-tandem type : 1 high-pressure cylinder, 1 intermediate-pressure cylinder, 2 low-pressure cylinders :—

Diameter of high-pressure cylinder, 23 inches ; ratio, 1·00 ; stroke, 5 feet.
Diameter of intermediate-pressure cylinder, 37 inches ; ratio, 2·60 ; speed, 60 revolutions.
Diameter of low-pressure cylinder, 42 inches ; ratio, 6·66 ; piston speed, 600 feet.

Rope pulley 30 feet diameter, grooved for 52 ropes 1⅜ inch diameter.
Rope velocity, 5,655 feet per minute.
Boilers.—Steel. 4 Lancashire type, 30 feet by 8 feet (one being spare). Pressure, 165 lbs. Furnaces, 39 inches diameter.
Economiser.—Green's type, 448 pipes in 7 groups of 64 pipes each. Feed temperature, 75° F. Delivery to boilers, 320° F.
Chimney.—210 feet high, 8 feet diameter inside at top.
Machinery.—96 cards (flat-revolving type), 50-inch cylinder by 45 inches wide ; 4 drawing frames, each 3 heads, 4 deliveries ; 12 drawing frames, each 2 heads, 8 deliveries ; 12 slubbing frames, 104 spindles each ; 20 intermediate frames, 140 spindles each ; 52 roving frames, 180 spindles each ; 140 spinning frames, 376 to 396 spindles each.

(*HEYWOOD DISTRICT.*)

Engines.—The triple expansion condensing engines of the Mutual Spinning Company of Heywood were tested by Mr. J. F. L. Crosland with the following results :—

High-pressure cylinder, 21 inches diameter ; ratio, 1·00 ; stroke, 6 feet.
Intermediate-pressure cylinder, 33 inches diameter ; ratio, 2·50 ; speed, 53 revolutions.
Low-pressure cylinders, 35 inches diameter ; ratio, 5·61 ; piston speed, 636 feet per minute.
Total indicated horse-power, 1,090. Boiler-pressure, 156 lbs.
Cylinder vacuum, 11·2 lbs. ; condenser vacuum, 12·2 lbs. ; injection, 101° ; hot-well, 133° ; steam (2·5 per cent. wet) per horse-power hour, 12·51 lbs. ; dry, 12·2 lbs.
Dry coal per I.H.P. hour, 1·37 lb.

Economiser.—288 pipes ; mechanical stokers.

Boilers.—Two Lancashire boilers, 30 feet by 8 feet ; 66·5 square feet grate surface. Feed to economiser, 130° ; to boilers, 304°. Heating surface : boilers, 2,016 feet ; economiser, 2,880 feet.
Coal : Bituminous slack, 5·6 per cent. ash ; evaporating from and at 212°, 10·36 lbs., of which 16½ per cent. due to feed-heater. Coal per square foot of grate, 24·16 lbs. I.H.P. of engines, shafting and belts on loose pulleys, 242.

Egyptian Yarn (Fine).

For spinning fine yarns an indicated horse-power of 1,900 is found to drive 132,000 mule spindles and other preparation machinery at the Irwell Bank Mill, near Bolton.

Weaving Shed.

(*BLACKBURN DISTRICT. YATES & THOM, ENGINEERS.*)

172 feet 6 inches by 136 feet, to contain 512 looms.

Boiler.—One, 30 feet by 8 feet, 100 lbs. steam pressure.

Economiser.—96 pipes.

Engines.—Compound side-by-side type.
High-pressure cylinder, 16 inches diameter } Stroke, 4 feet ; revolutions, 55.
Low " " 28 " " }
Fly rope pulley, 20 feet diameter ; 7 grooves for 1⅝ rope.

The following are plants completed at Great Harwood and Leigh, by Messrs. Yates & Thom just before the war.

Great Harwood.

Three weaving sheds, each containing between 800 and 1,000 looms, 36 inches to 58 inches wide.
Horizontal cross compound engine cylinders, 17 inches and 34 inches diameter ; 3 feet 6 inches stroke, 450 i.h.p. ; 75 revolutions per minute.
Economiser, 128 pipes.
One boiler, 32 feet long ; 8 feet 6 inches diameter ; 160 lbs. pressure.
Fly rope pulley, 14 feet diameter, for 14 1¾-inch ropes.

Leigh.

Two weaving sheds, each containing 900 looms, 32 inches to 57 inches wide.
Horizontal cross compound engine cylinders, 16 inches and 32 inches diameter ; 3 feet 6 inches stroke ; 400 i.h.p. ; 80 revolutions per minute.
Boiler, 30 feet long ; 8 feet 6 inches diameter ; 180 lbs. pressure.
Economiser, 96 pipes.
Fly rope pulley, 15 feet ; 11 1¾-inch ropes.

Spinning and Weaving Mill.

Bury.

26,000 mule spindles, 32,000 ring spindles, 10's to 44's counts.
750 looms.
Horizontal cross compound engine cylinders, 33 inches and 66 inches diameter ; 5 feet stroke ; 2,000 i.h.p. ; 65 revolutions per minute.
Five boilers, 30 feet long ; 8 feet diameter ; 175 lbs. pressure.
Economiser, 480 pipes.
Fly rope pulley, 24 feet diameter for 46 $1\frac{3}{4}$-inch ropes.
Superheaters.

Mule Spinning Mill.

(OLDHAM DISTRICT. POLLIT & WIGZELL, ENGINEERS, SOWERBY BRIDGE.)

Mill 5 floors and cellar, 355 feet long, 129 feet wide inside ; 107,000 spindles, counts 8's to 40's ; one-third weft, two-thirds twist ; 1,650 indicated horse-power.

Engines.—Cross compound horizontal :—
High-pressure cylinder, 26 inches diameter
Low " " 52 " " } each 5 feet stroke, 75 revolutions per minute.
Flywheel 22 feet diameter, turned for 36 ropes $1\frac{5}{8}$ diameter. Weight of wheel-rim 36 tons.
Coal used for all purposes, 70 tons in summer, 84 tons in winter, per week.

Boilers.—6 Lancashire, 5 working, 1 cleaning ; 30 feet long, 8 feet diameter ; working pressure, 160 lbs. superheated.

Economiser.—Green's, 480 pipes.

Chimney.—7 feet diameter, 180 feet high ; main flue 8 feet high, 4 feet wide.

Mill Shafting.—Card-room shafts, 220 revolutions with 18-inch pulleys for drawing, roving and intermediate frames ; 170 revolutions for cards with 16-inch pulleys. Mule-room shafts 300 revolutions with 30-inch pulleys.

In the Yorkshire district it is not unusual to carry on cotton spinning in a shed of one floor as in India.

Ring Spinning Mill.

(POLLIT & WIGZELL, ENGINEERS, SOWERBY BRIDGE.)

One-floor shed, 203 feet wide, 346 feet 6 inches long ; in bays, lengthway, 10 feet 6 inches pitch ; 36,000 spindles, counts 0's to 32's ; average indicated horse-power 995.

Engine.—Tandem horizontal compound :—
High-pressure cylinder, 21 inches diameter
Low " " 42 " " } each 5 feet stroke, 75 revolutions per minute.
Flywheel 20 feet diameter, grooved for 26 ropes $1\frac{5}{8}$ diameter. Weight of rim, 30 tons.
Coal used for all purposes, 40 tons in summer, 58 tons in winter, per week.

Boilers.—3 Lancashire, 30 feet long, 8 feet diameter ; working pressure, 160 lbs., superheated

Economiser.—Green's, 272 pipes.

Chimney.—5 feet 6 inches diameter, 150 feet high ; main flue, 7 feet 6 inches high, 3 feet 3 inches wide.

Mill Shafting.—Card shaft, 175 revolutions with 17-inch pulleys ; drawing, roving, and intermediate frame shafts, 254 revs. with 27-inch pulleys ; spinning shaft, 254 revs. with 42-inch pulleys. The last seven bays of the shed are utilised for winding, reeling, and warping.

Boilers.

A Lancashire boiler to work at 160 lbs. pressure for a modern cotton-mill will usually be 30 feet long, 8 feet 6 ins. diameter, shell and end plates of $\frac{13}{16}$-inch steel with double butt strips, which in good work may be of equal breadth and treble riveted ; or the outer strap may be narrower than the inner strap and having only the double riveting. Furnaces and flues $\frac{9}{16}$ inch plate. The whole of the steel to be of 26 to 30 tons tensile strength, and to elongate not less than 20 per cent. in a length of 10 inches. For furnaces, steel with a tensile strength up to 32 tons is sometimes allowed.

Economisers.

THE 'GREEN' ECONOMISER.

(See Section XXX, Part II.)

Main Driving Ropes.

The main driving of cotton-mills is usually by cotton ropes of $1\frac{3}{8}$ inch to $1\frac{3}{4}$ inch diameter, the present tendency being towards the smaller diameter. The following tables are deduced from the weights of pure cotton ropes made by a Lancashire firm :—

Diameter of Rope in inches	$\frac{3}{4}$	$\frac{7}{8}$	1	$1\frac{1}{8}$	$1\frac{1}{4}$	$1\frac{3}{8}$	$1\frac{1}{2}$	$1\frac{5}{8}$	$1\frac{3}{4}$	$1\frac{7}{8}$	2
Weight per foot in pounds	·18	·25	·33	·40	·50	·60	·72	·84	·98	1·125	1·3
Diameter of smallest Pulley advisable	22″	25″	30″	34″	37″	42″	45″	48′	52″	57″	66″
Total stress in Rope in pounds	110	150	195	246	300	360	430	500	600	675	780
I.H.P. at 5,000 feet velocity	9	12	16	20	25	30	36	42	49	56	64

There is no practical difference in the power of ropes between 3,600 feet and 5,600 feet velocity. In Yorkshire, leather ropes $1\frac{1}{2}$ inch square are used, and will drive 80 i.h.p. per rope.

Cotton Yarn Measurement.

Cotton yarn is measured by the hank of 840 yards of single thread, and is said to be of 40's or 60's counts, when 40 hanks or 60 hanks weigh 1 lb. A lea is one-seventh of a hank or 120 yards. A wrap reel is 54 ins. circumference, so that 80 revolutions wind one lea and the skein thus wound is what is tested for strength. The softness of yarn varies with the number of turns per inch put into it. For equal quality in different counts the turns must vary as the square root of the counts. Thus turns per inch $= c\sqrt{\text{counts}}$.

For Indian and American cotton, $c = 3{\cdot}75$ for mule twist ; $3{\cdot}25$ for mule weft ; $4{\cdot}00$ for ring twist.

For Egyptian cotton the above values of c become $3{\cdot}606$, $3{\cdot}183$, and $3{\cdot}606$ respectively. Thus 50's American ring twist requires full 28 twists per inch.

List of Machinery in a Lancashire Mill, showing Average 30's Twist on Mules or Ring-frames, with approximate production at each process, speeds, etc.

77,000 Mule spindles for 28's to 32's (average 30's) twist spun counts at 31 hanks per spindle calculated to produce 79,566 lbs. of yarn per week of $55\frac{1}{2}$ hours from American cotton, $4\frac{1}{4}$ hanks single roving, or,

52,800 Ring spindles for 28's to 32's (average 30's) twist spun counts, at 45 hanks per spindle, calculated to produce 79,200 lbs. yarn per week of $55\frac{1}{2}$ hours from American cotton, $4\frac{1}{4}$ hanks single roving.

3 Hopper bale breakers, 36 ins. wide.

3 Automatic hopper feeders, 36 ins. wide, with filling apparatus.

3 Single Crighton cylinder parts, with valves and pipes to the exhaust opener, and lap machine.

3 Exhaust openers and lap machine, 48 ins. wide, for 46-in. laps, with lattice feeder, 4 ft. ntres, and dust trunks.

7 Single-finisher scutchers and lap machines, 46 ins. wide, for 45-in. laps, feeder for 4 laps. Lap 14 ozs. per yard.

1 Roving waste-opener and feeding-machine.

Details.	Hanks Roving.	Speed.	Prod. Lbs.	Hanks per Week.
			Each.	
108 Single cards, 45″ on wire, 50″ cyl., 106 s.s. flats, $1\frac{3}{8}$″ wide	0·15	Cyl. 170 r.p.m.	774	116
27 Drawing-frames, 2 heads of 4 deliveries = 27 finishing deliveries	0·13	350 r.p.m. of $1\frac{1}{2}$″ front roller	1150	149
9 Slubbing-frames, 96 spindles each 10″ × $5\frac{1}{2}$″ bobbins × 19″ staff	0·675	600 r.p.m. of spindle	94·8	59·2
17 Intermediate-frames, 140 spindles each 10″ × $4\frac{3}{4}$″ bobbins × $26\frac{3}{8}$″ staff	1·60	750 r.p.m. of spindle	34·1	54·5
42 Roving-frames, 180 spindles each 8″ × $3\frac{5}{8}$″ bobbins × $20\frac{1}{2}$″ staff	4·25	1,100 r.p.m. of spindle	10·6	45·1
74 S.A. mules, 1,100 spindles each 54″ stretch	30's, etc.	10,000 r.p.m.	1·03	31
120 Ring-frames, 440 spindles each $2\frac{1}{2}$″ distance, $1\frac{5}{8}$″ rings, $6\frac{1}{2}$″ lift	30's	9,000 r.p.m. of spindle	1·5	45

The above includes for a loss of 1 per cent. at each process, from the card-sliver to the spindle point.

In a modern mill the handling of cotton is reduced to a minimum. The bales of raw cotton are opened and slabs of the fibre flung into the bale-breaker, which delivers either to a mixing-bin or direct to a hopper-feeder, wherein the fibre is automatically regulated to weigh a given weight per yard. Thence it passes forward and is made into laps or rolls. These are removed by hand to the finisher scutcher whence the laps are run by a vertical tramway to the carding engines by hand. The cans of sliver made by the cards, and by the drawing frames and the bobbins, filled at all subsequent operations, must be moved and removed by hand.

The most modern mills are arranged, where possible, with all the card-room or preparation machinery on one floor. It is very usual to extend the ground floor by means of a shed extension along one side of the mill to enable this to be done. Usually the carding-engines are placed under this extension.

For fine counts, 120's to 140's, such as are now much spun in Oldham from Egyptian cotton the card sliver is combed before being drawn, and the modern tendency is to use combs for even coarser yarns. Generally, owing to Indian competition, the tendency in Lancashire is all in the direction of finer counts.

Horse-Power to Drive Cotton Machinery, with Speeds for Pulley.

(Bolton figures.)

	I.H.P.	R.P.M.
Hopper bale breaker	2 to $2\frac{1}{2}$	450 to 500
Porcupine opener	2 to $2\frac{1}{2}$	800
Hopper feeder	$1\frac{1}{2}$	225
Vertical opener, single	4	1,000
„ „ double	8	1,000
Exhaust opener	2	900
Opener with hop machine	12	1,200
Single scutcher	4	1,000 to 1,200
Double „	8	1,000 to 1,200
Carding engine	$\frac{3}{4}$	160 to 180
Sliver-lap machine	$\frac{1}{2}$	200 or 500
Ribbon „	1	262
Single-nip comb	$\frac{5}{8}$	305
Double-nip „	$\frac{3}{4}$	229
12-delivery drawing frame	1	150 to 300
Slubbing frame 90 spindles	2	200 to 300
Intermediate „ 120 „	2	300 to 385
Roving frame 150 „ / Jack „ 200 „	2	310 to 455
Self-acting mules	1 h.p. per 120 to 140 spindles	
Cop winding	1 h.p. „ 300 „	120
Ring frame	1 h.p. „ 90 to 100 „	
„ doubler	1 h.p. „ 55 to 65 „	
Drum winder	1 h.p. „ 100 drums	400 to 600
80-hank reel	$\frac{1}{2}$	250

The power required tends to be more or less according to the speeds of spindles, beaters, etc. For finer counts spindles run at higher speeds, but machinery generally is lighter.

Electrical Driving of Cotton Mills.

The load factor of a cotton mill is probably 90 to 95 per cent. This renders electrical driving of doubtful economy. It cannot be economically done from an outside power station, for this would be doing well if it had a 40 per cent. load factor. A cotton mill with its own generating plant can work more cheaply than by purchased current at a price that would pay an outside power station to charge. Then the transmission line is costly.

A group of mills within a small radius such as may be found in places might perhaps be economically driven from one central power house close to all the mills. But in electrical driving the generator is more costly than the rope rim, and the motors, if on line shafts, are more costly than the driven rope pulleys. The transmission losses and the generator and motor losses appear to be greater than the loss by rope driving, and where each machine has its own motor this and the transmission system seem to cost much more than shafting and pulleys. Where the motor stands on the floor at the end of a spinning or speed frame it compels the cutting out of several spindles, reducing the output capacity several per cent., or by fully as much as it is claimed each spindle will give an increased output as compared with an ordinary mill. But so far this increased output has been only demonstrated as between modern high-speed engines with electrical driving and old slow-speed engines in some out-of-date rope-driven mill. No comparisons are put forward with modern rope-driven mills with modern high-speed engines.

There are two systems of electric driving : (*a*) with the usual line shafts, each shaft with an electric motor taking the place of the usual rope pulley ; (*b*) with motors to each machine. And there may be (*c*) a mixed system on which there are line shafts for certain classes of work and separate motors for other machines. Rapid acceleration is claimed as an advantage of electrical driving. This, of course, demands motors much larger and more powerful than are merely necessary to drive the frame at its normal speed. The same acceleration may be secured with belt driving if the belts are made sufficiently larger than they need to be for the constant normal speed. Shafting does not require very much power to drive it, and where machines such as ring frames are closely spaced under a shaft, as are ring frames, it is difficult to see much benefit from electric driving of these machines, which do not stop until the bobbins are full. But with speed frames which must stop for every broken sliver it may be convenient that each machine should have its own motor. Mules which have an enormous and rapid variation of driving torque are badly suited for separate motors, and appear better driven from a line shaft. Given sufficient belt power any machine can be accelerated as rapidly as desired, and no single machine will be felt by the main engine any more than if accelerated electrically.

The abolition of belts is an advantage of some value in the separate motor system, but so far the experience of electrical driving has not been such as to warrant other than the most careful consideration of each case on its merits, and by an engineer who is a textile man first and an electrical engineer second. The following are estimates of cost of rope and electrical driving which may help the consideration of any particular case. The estimates are based on the driving of a 110,000 spindle mill (Bolton-fine-Counts) :

(Pre-war Prices.)

(*a*) *Rope Driving.*

Capital outlay—	£	*s.*	*d.*
Engine 1,500 i.h.p. and piping in engine-house	4,765	0	0

Insurance: motors, £60; transformers, £15; gearing, £40; buildings, £10.	125	0	0
Interest and depreciation on £9,280 at 12 per cent.	1,112	0	0

(*c*) *Running Costs*—continued.

	£	*s.*	*d.*
Current : average load 900 k.w., including lighting, based on uniform charge of 0·5625*d.* per hour	5,906	0	0
	£7,680	10	0

Equal to 0·657 pence per k.w. hour.

From the foregoing it would appear that if current can be bought for about 0·4*d.* per unit the driving by a public supply would cost the same as by ropes.

In the foregoing estimates of running costs, the boiler cleaning charges are omitted, the extra cost of this for (*a*) and (*b*) being about balanced by the omission of the wages of the stoker of the heating boiler in case (*c*). It is at present doubtful if current can be sold at a profit for 0·4*d.* per unit by any power station. The situation is made worse by the necessity for a heating boiler and chimney, &c., for case (*c*).

On the other hand driving electrically dispenses with the rope race which divides a mill halfway across into two sections, and it sets free the area of the race for machinery and increases the production within a given total area. But the real success of the system would come where a group of mills could be driven from a joint-power plant in the middle of the group, especially if the warming could be done from the same boilers. There is very little in the claim for steadier driving, this being merely a question of flywheel energy and cyclical regularity equally obtainable with ropes as electrically. No weight must be given to comparisons with old mills driven by old slow engines. Engineers should study the Brown Boveri ring frame, for which electricity does what is otherwise impracticable. In this machine the spindle speed is varied by moving the brushes of the motor so that the tension on the yarn is kept uniform at all stages of the bobbin. This cannot be done except by electrical means.

PAPER MILLS.

See 'Modern Paper Mill Plant,' *Proceedings of the Institution of Mechanical Engineers*, No. 3, 1926.

OIL MILLS.

The Manufacture of Vegetable Oils.

There are two methods of extracting oil from vegetable seeds and nuts. These are by means of hydraulic presses and by chemical solvents.

Two types of hydraulic presses are used. The Anglo-American, which has corrugated plates, between which the meal is confined in cloths, the sides being open ; and the 'cage' press, the box of which is built up of narrow steel bars held in a vertical position by weldless steel hoops, spaces being left between each bar for the escape of the oil, the solid matter, in the form of a round cake, being retained in the box.

The Anglo-American system is usually employed for seeds which do not contain more than 35 per cent. of oil; as the meal is confined between open plates it is difficult to prevent its escape, and the wrappers are soon destroyed when a large percentage of oil is present. For this reason a 'cage' press should be employed for all materials rich in oil.

The 'cage' press has the further advantage that a cold-drawn oil can be produced, and also double pressing can be resorted to, the second pressing being performed in either a 'cage' press or Anglo-American press.

In the expression of oil from seeds there are three main operations : crushing, heating, and pressing.

The crushing is of great importance; the oil cells must be thoroughly crushed and burst open. Unless this is effectively done it will be impossible to express the maximum amount of oil. The crushing rolls are usually five in number, superimposed, the seed being deflected by scraper plates, so that it is made to pass between the various rolls, and is thus subjected to four crushings, each receiving a heavier pressure than the preceding one. The heating is done in a mild steel kettle having a steam jacket, a mechanical stirrer, and a steam spray to give the necessary moisture to the meal.

The preliminary treatment of the seed is the same for Anglo-American and 'cage' presses.

For Anglo-American presses the heated meal has to be moulded, compressed, and wrapped in a cloth before it can be placed in the press, the usual number of cakes in each press being sixteen. The cakes leave the press with very oily edges; these have to be trimmed off by a paring machine, the oily edges being returned to the kettle for further treatment.

With 'cage' presses the meal passes directly into the box in measured quantities, a plate dividing each charge. With some seeds flat cloths are also placed between the meal and the plate to prevent cake from adhering to the plate and to assist the flow of the oil. The cakes leave the box in a finished state.

A small self-contained Anglo-American mill with two presses made by the Mirrlees Watson Co., Ltd., has a capacity of 7½ cwts. of seed per hour, and consists of the following parts:—

1 set of crushing rolls, five high, 12 ins. diameter, 18 ins. long.
1 meal-heating kettle, 42 ins. diameter, 27 ins. deep.
1 cake-moulding machine with a steam compressor.
2 hydraulic presses with rams 16 ins. diameter, working pressure 2 tons per sq. in., each press to make sixteen cakes per pressing.
1 cake-paring machine with fine reducing apparatus.
1 set of hydraulic pressure pumps, valves, and pipes.
1 oil collecting and settling tank.
1 rotary oil pump, and elevators to raise the seed to the rolls and meal to the kettle.

The parts are carried on a foundation plate, geared together and driven by a single belt. A smaller mill is also made with one press only. For larger capacities the machines are built separately and driven by belts from a shaft carried upon girders. They are fitted up in sets of four and eight presses, with capacities of 15 cwts. and 30 cwts. of seed per hour. The rolls are 16 ins. diameter, 48 ins. long.

For the eight-press and larger mills hydraulic accumulators are fitted, working at 500 to 600 lbs. and 2 tons per sq. in. The ballast is of sand contained in a mild steel case which is guided by mild steel guides. The sizes generally used are 9 ins. and 3 ins. diameter by 8 ft. stroke for the small plant, and 14 ins. and 4 ins. diameter by 10 ft. stroke for the larger plants.

Small self-contained mills with 'cage' presses are made by the Mirrlees Watson Co., Ltd., with capacities of 1½, 3, and 6 cwts., respectively. The rolls are of the Anglo-American type; the presses work at 2 tons per sq. in. and exert a pressure of over 35 cwts. per sq. inch on the cakes.

The 1½-cwt. mill has rolls 8 ins. diameter, 8 ins. long; kettle 21 ins. diameter, 18 ins. deep; press ram 10½ ins. diameter; box 11 ins. diameter, 54 ins. deep. The 3-cwt. mill has rolls 8 ins. diameter, 12 ins. long; kettle 27 ins. diameter, 20 ins. deep; press ram 13 ins. diameter; box 14 ins. diameter, 60 ins. deep. The 6-cwt. mill has rolls 8 ins. diameter, 18 ins. long; kettle 39 ins. diameter, 21 ins. deep; two presses with rams 13 ins. diameter; boxes 14 ins. diameter, 60 ins. deep.

The mills are complete with hydraulic pumps, valves, and pipes, the machines being geared together and driven by a single belt. The plants are also provided with reducing mills, so that large nuts, copra, etc., can be broken up previous to being passed to the crushing rolls. The cakes from the first pressing can also be broken up when double pressing is resorted to. Larger mills have independently driven machines and presses with boxes up to 19 ins. diameter by 9 ft. deep.

The expressed oil should be passed through a filter press to remove the sediment and produce a bright, clear oil. The filter press is composed of a number of plates with raised pyramid-shaped projections which support the cloth placed over each plate, the plates and cloth being securely clamped together. The oil is forced through the cloth and flows past the projections to the outlets at the bottom, and is collected in a trough fixed to the frames.

The oil passes through a further process of refining to remove the fatty acids and colouring matter, and when required for edible purposes is deodorised to remove the characteristic odour of the oil.

For the solvent process the seed must first be crushed, the meal is then placed in closed vessels, and the solvent, usually benzine, allowed to percolate through it in order to dissolve out the oil content. The mixture of oil and solvent is subjected to distillation—the solvent, being condensed, is used over again, and the oil is heated and steamed to remove the final traces of the solvent.

The meal after the solvent has been drained from it is also heated and steamed to remove all traces of solvent. Large plants are made with a series of vessels so that the solvent can be passed through a number and become heavily impregnated with oil before it is passed to the distiller. The residue from the process is in the form of meal, and should not contain more than about 2 per cent. of oil.

CANE-SUGAR MACHINERY.

For large sugar works, the canes are brought from the field to the factory by rail in trucks which are weighed and unloaded mechanically on to a carrier which continuously conveys them to the

Crushing Mills.

These usually comprise a pair of deeply serrated preparing rollers followed by several sets of three-roller crushing mills in tandem, and steam driven through heavy spur gearing.

The cane in transit through these successive mills is macerated with hot water, enabling ordinarily a juice extraction of over 80 per cent. on the weight of the cane to be obtained. This crushed cane (technically termed megass or bagasse), leaving the final mill with 45 to 50 per cent. of contained moisture, is continuously fed into special boiler furnaces and utilised for steam generation, supplying frequently the entire factory requirements.

MULTIPLE CRUSHING MILLS.

(The Mirrlees Watson Co. Ltd., Glasgow.)

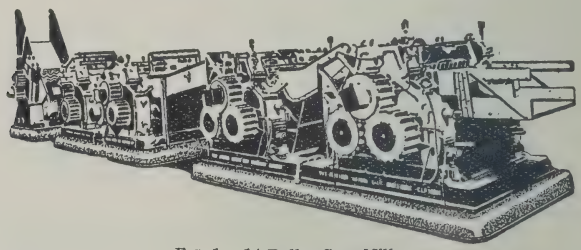

FIG. 1.—14-Roller Cane Mill.

Mill Rollers Dia. and Length.	Tons of Cane Crushed Hourly.		Engine Dia. and Stroke.

36×84	64	72	38×60	34×60

The mill capacity varies according to the class of cane crushed.

Vacuum Evaporators.

The cane juice expressed by the mills is clarified (by liming, heating, subsiding, and filtering) and then concentrated, in vacuo, to about one-fourth its original volume. The apparatus commonly used is a triple or quadruple effect, in which exhaust steam is used as the heating agent for the juice in the first vessel, whose vapour, under a reduced temperature, boils the partly concentrated in the second vessel, which again liberates vapour for boiling the still denser juice, under a still lower temperature in the succeeding vessel, which, in the case of a triple apparatus, is under a high vacuum and consequently low temperature. In a quadruple effect the principle is similar.

Mirrlees

Vacuum Pans

For the crystallization of liquids under high vacuum.

Our designs provide for rapid circulation with well distributed heating surface to ensure rapid boiling and economical steam consumption.

13 0	1,725	2,300	9,850
14 0	2,025	2,700	11,540
15 0	2,360	3,150	13,400

The resulting massecuite is discharged into crystallisers, thence to centrifugal sugar-curing machines, in which the molasses is separated from the crystals, which are thereupon dried and bagged for transport.

Vacuum Evaporators for Trade Liquids.

In the concentration of trade liquors by evaporation, it is generally important that this should be not only economically but also rapidly effected under low temperature, as many liquids exposed to heat deteriorate. Hence the extended adoption of multiple-effect evaporators on the

horizontal tube type of the Mirrlees Watson Co. Ltd., which, having a rapid flow of liquid through their evaporating tubes, meet these requirements with the minimum of deposition on the heating surfaces.

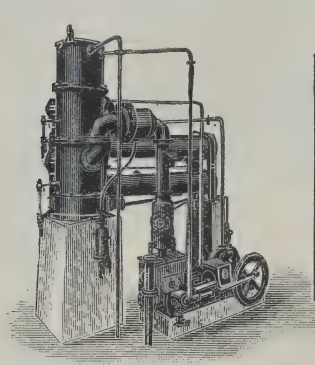

FIG. 4.—Double Effect.

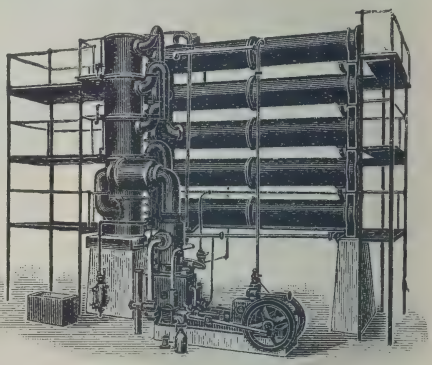

FIG. 5.—Quintuple Effect.

For bark and wood extracts, gelatine, glue, glucose, glycerine, and similar liquids of a viscid nature, a wide temperature difference between the vessels is desirable, hence the use of a double effect arrangement (fig. 4); their sizes range from 50 to 1,000 gallons hourly.

For soda ash recovery in paper mills, caustic soda, caustic potash, meat extract, distillery refuse, and other liquids readily amenable to concentration, triple, quadruple, quintuple (fig. 5), and sextuple (fig. 6) installations are in use; their sizes range from 100 to 3,000 gallons hourly.

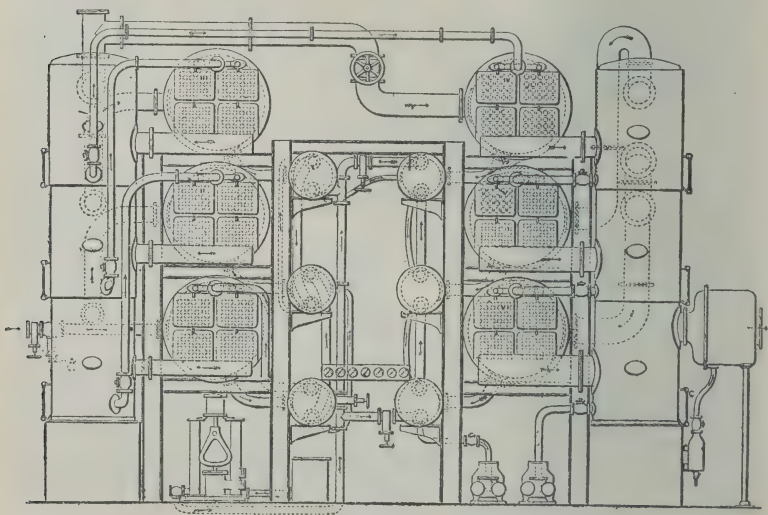

Fig. 6.—Sextuple-Effect Evaporator for Caustic Soda Lye.

Water Distillers.

To meet the demand for large quantities of distilled water at the lowest cost, the Multiple-Effect system of evaporation, extensively used in sugar manufacture, has also been applied largely, by the Mirrlees Watson Co. Ltd., to fresh-water distillers at home and abroad.

The principle on which multiple-effect evaporation is based is that the boiling point, and consequently the vapour temperature of liquids, varies with the surrounding pressure; the lower the pressure, the lower the boiling temperature; this principle is applied by working with diminishing pressures in the successive vessels of the multiple-effect evaporator.

Evaporators on the above principle are extensively used, but considerable experience is required so to proportion the various evaporating and condensing surfaces to secure the highest economy.

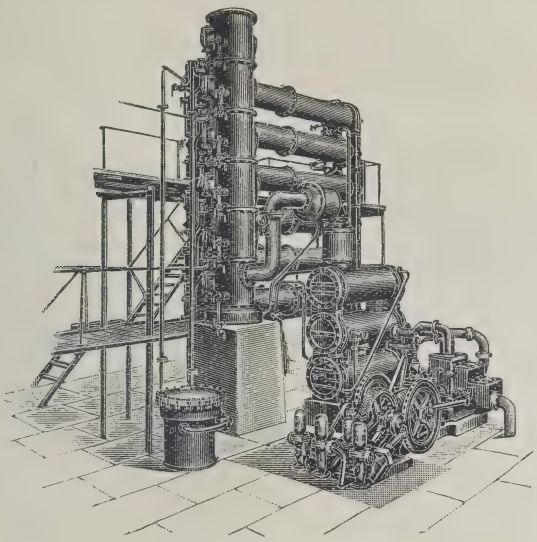

FIG. 7.—Sextuple Distiller.

Fig. 7 shows a sextuple-effect fresh-water distilling plant, which has been brought to a high state of efficiency, producing 44 lbs. of gained water (not including the drip from first vessel, which goes back direct to the boiler) per lb. of coal consumed.

Plants of this design are made to produce from 25 to 350 tons of distilled water per twenty-four hours. This type of distilling plant has been adopted by the British and other Governments.

For countries where earthquakes occur such apparatus is arranged with its evaporating vessels on a horizontal plane in place of the super-imposed type illustrated by fig. 7.

(*The Mirrlees Watson Co. Ltd.*)

NOTE ON CONDENSERS.

Great caution should be exercised in guaranteeing the efficiency of condensers which are used for other purposes than the condensation of exhaust steam from steam engines, as for example the exhausting of vacuum pans for sugar manufacture. In such cases it often happens that far more air is present than is the case with ordinary exhaust steam, and consequently the condenser may prove unequal to the task for which it was guaranteed. Those who quote prices or guarantee a particular efficiency in the case of a condenser should make it plain that the 'steam' to be condensed must only contain a certain (specific) quantity of air.

CRANES.

(Contributed by John H. Huntley, M.I.E.S.)

General Notes on Cranes.

The selection of a crane for any particular service is governed by several factors, such as load, space available, power at disposal of user, frequency and speed of operation, height of lift, duration of service and cost.

Cranes can be operated by manual, steam, hydraulic, pneumatic, or electric power, or by a combination of these powers.

In power stations, stores, and places where an occasional lift is all that is required, a hand crane is quite suitable, even for loads up to 20 or 30 tons, but for frequent operation, or where the load has to be moved a considerable distance, it is advisable to instal a power-driven crane, even for a load of a few hundredweights, as the saving in time and labour soon pays for the difference in initial cost.

The electric crane has the following points in its favour :—

1. Simplicity of operation.
2. No power consumed whilst crane is standing.
3. Power used varies in proportion to load.
4. Always ready for starting up.

The steam crane has the advantage that it can be used wherever a supply of fuel and water is available, but time is lost in raising steam, and fuel is consumed in keeping up steam between the lifts.

Hydraulic cranes are only economical in operation when constantly working under full load, as the water consumption is the same for light or heavy loads, although by means of double-power rams attempts have been made to overcome this defect. Trouble is caused by frost in exposed situations. Hydraulic cranes are still largely used in shipyards and boiler shops, for handling plates, portable riveters, etc., where a small lift at slow speed is required. The working hydraulic pressure is usually 1,500 lbs. per sq. in., but may be as high as 2 tons per sq. in.

Pneumatic power is applied only to small hoists and pulley blocks, the air pressure being usually about 100 lbs. per sq. in.

Petrol or Paraffin engines have been applied for driving small portable jib cranes, and experience has proved that the nominal horsepower of the engine should be at least 50 % more than the actual brake horsepower required in order to have a sufficient margin for acceleration.

Hand Cranes.

The ordinary height of handle above ground should be 3 ft.; radius of circle described by handle, not more than 18 ins.; 16 ins. is a usual length. Angle of jib, 45°.

Each man working at the handle of a crane will exert a force of 15 to 20 lbs., exclusive of friction.

If W = weight to be lifted by crane in lbs., P = force applied to handle in lbs., D = diameter described by handle in inches, n = number of revolutions of handle to one of barrel, B = diameter of barrel in inches, then

$$B = \frac{D \times P \times n}{W}. \qquad D = \frac{W \times B}{P \times n}. \qquad n = \frac{W \times B}{D \times P} \qquad P = \frac{W \times B}{n \times D} \qquad W = \frac{P \times D \times n}{B}$$

OVERHEAD TRAVELLING CRANES.

For service inside buildings or where the site conditions permit of the construction of a gantry the overhead travelling crane has proved to be the most efficient appliance. For outside work a Goliath crane is often equally serviceable, and has the advantage of a lower first cost than an overhead crane with gantry.

For hand cranes up to 40 ft. span and loads up to 5 tons, a single girder crane can be adopted, but for longer spans or heavier loads it is advisable to use the double girder type to obtain lateral stiffness.

Light cranes are usually operated from the floor level by hanging chains, but for cranes above 10 tons it is advisable to work them from the crane platform. The pull on a hand chain should not exceed 40 lbs. per man, and for crank handles not more than 25 to 30 lbs. per man. The handles should have a radius of 16 ins. to 18 ins. and the centre be at a level of from 2 ft. 6 ins. to 3 ft. above platform level.

Travelling wheels for both crab and crane are usually of cast iron, and should be fitted with ball or roller bearings.

The hoisting gear should be efficient, preferably with machine-cut teeth, pinions of mild steel, wheels of cast iron, and should be fitted with a self-sustaining brake which requires to be released by the operator before the load can be lowered, but which is inoperative in the hoisting direction. This condition can be obtained by an internal ratchet or a screw disc brake.

Worm gear should have a coarse pitch and the sustaining power of the crane should not be dependent upon the inefficiency of the gear.

OVERHEAD ELECTRIC CRANES.

For engineering shops, foundries, steelworks, etc., the overhead electric travelling crane is unequalled for general service.

The motions of hoisting, traversing and travelling are generally arranged, and a separate motor should be fitted for each motion. An auxiliary hoist having a lifting capacity of about one quarter the main hoist is desirable on cranes above 40 tons capacity, and should be operated by an independent motor.

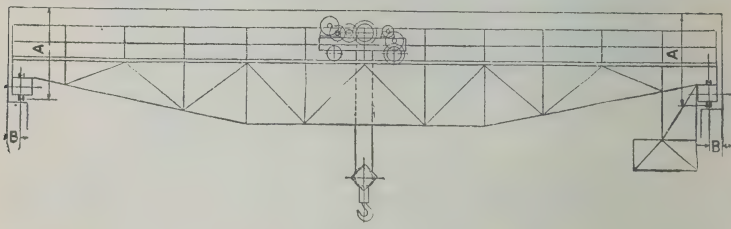

FIG. 1.

The following are particulars of standard 3-motor overhead travelling cranes (fig. 1), 30 ft. lift :—

The above table is for cranes on four travelling wheels.

For 70-ton cranes and upwards the usual practice is to mount the crane on eight travelling wheels, and the wheel loads in the following table are based on this. The column headed 'Centres of Wheel Bogies' indicates the distance between the centre of each pair of wheels in each end carriage, and the following column gives the distance between the two wheels of each pair:—

Size.	Span.	Head-room A.	End Space B.	Crs. of Wheel Bogies.	Bogie Wheel Centres.	Max. Press. per Wheel.	Wt. of Crane.	Speeds in F.P.M.			Falls of Rope.

NOTE.—The headroom figures allow for about 3 ins. clearance and the end space for about 1½ in. clearance.

For short-span cranes of small size, a pair of 'H' beams make an economical set of girders, but the span should not exceed sixty times the width of the flange of one girder. For cranes up to 60 ft. span the most economical construction is the trapezoidal single web girder, with lattice auxiliary connected to the main girder by horizontal and diagonal bracing. This makes a very stiff construction, is easy to manufacture, and all surfaces are accessible for painting. The platform and travelling gear can be well supported by bearers between the main and auxiliary girders. For long spans and for outside service it is desirable to make the girder of the lattice

FIG. 2.

(See page 807.)

type to reduce weight and wind surface. The depth of the girder is usually made one-twelfth the span. The maximum bending moment due to the crab, assuming each wheel equally loaded, is given by the formula :—

$$\frac{W}{28}\left(S - \frac{B}{2}\right)^2 \text{ ft. tons,}$$

where,

W = load per wheel in tons ; S = span in feet ; B = wheel base of crab in feet.

To this must be added the bending moment due to the deadweight of the girder and travelling gear. The modulus of the girder section should be such as to give a stress of between 5 and 6 tons per sq. in. The stresses in lattice girders are best determined by graphic methods.

The end carriages can be constructed of channels, and built up of plates and angles, when larger sections are required. They should be connected to the girders by large gusset plates, and fitted bolts to prevent cross winding. The wheel base should preferably be one-fifth to one-sixth of the span.

Rail wheels should be of cast steel, or of cast iron centres with steel tyres shrunk on. The width of the rolling surface of the rail is an important point, and for heavy loads a rounded surface should be avoided. The safe load on a wheel may be arrived at by the following empirical formula :—

For cast steel wheels, safe load in pounds = $800 \times W \times D$,

,, steel tyred ,, ,, ,, ,, = $1{,}200 \times W \times D$,

where,

W = width of rail face in inches ; D = dia. of wheel in inches.

Rails for heavy cranes are now rolled with a working face of 6 ins. and weight of 265 lbs. per yard.

To calculate the power required to travel a crane, a tractive force of from 60 to 70 lbs. per ton is usually taken, and for outside service the effect of wind pressure must be considered.

To prevent cross winding the cross shaft should be stiff enough to avoid undue torsional deflection when the driving wheels are unequally loaded due to the crab being at one end of the span. A foot brake should be fitted to the cross shaft on cage control cranes and a solenoid brake fitted to the motor shaft on all cranes working in the open.

The crab frame should be built up of steel sections well stiffened to form a rigid support for the motors and gearing. The traversing wheels should be of cast steel or have steel tyres, the latter only being necessary on crabs of the largest size.

It is unnecessary to fit a brake to the traversing motion unless the speed exceeds 100 ft. per minute, when a solenoid brake can be fitted.

The load is preferably lifted on wire ropes winding on to a cast iron drum rotated by gearing, the number of falls of rope depending upon the load. For cranes up to 3 tons capacity, the load may be lifted on two falls winding one fall on to the barrel. Where four or more falls of rope are used, two falls should wind on to the barrel, which should have right and left-hand spiral grooves and thus keep the load central between the girders.

The efficiency of the gearing varies from about 75 per cent. on small cranes to 65 per cent. on large cranes. A convenient rule to determine the horse-power of the hoisting motor is

$$\text{H.P.} = \frac{\text{foot-tons per minute}}{10}.$$

The speeds of working given in the table, pp. 802, 803, are suitable for general engineering shop work, but for steelworks very much higher speeds are used, and as continuous night and day service is the general practice in these works the design of the crane should be specially considered and made very robust.

All cranes are preferably fitted with two brakes, one of which should be an automatic solenoid brake; the type of the other brake will depend entirely on the service for which the crane is used.

Fig. 3 shows a small crab made by Messrs. Babcock & Wilcox. The framework consists of mild steel plates or channels connected by stretchers which support the motors and the

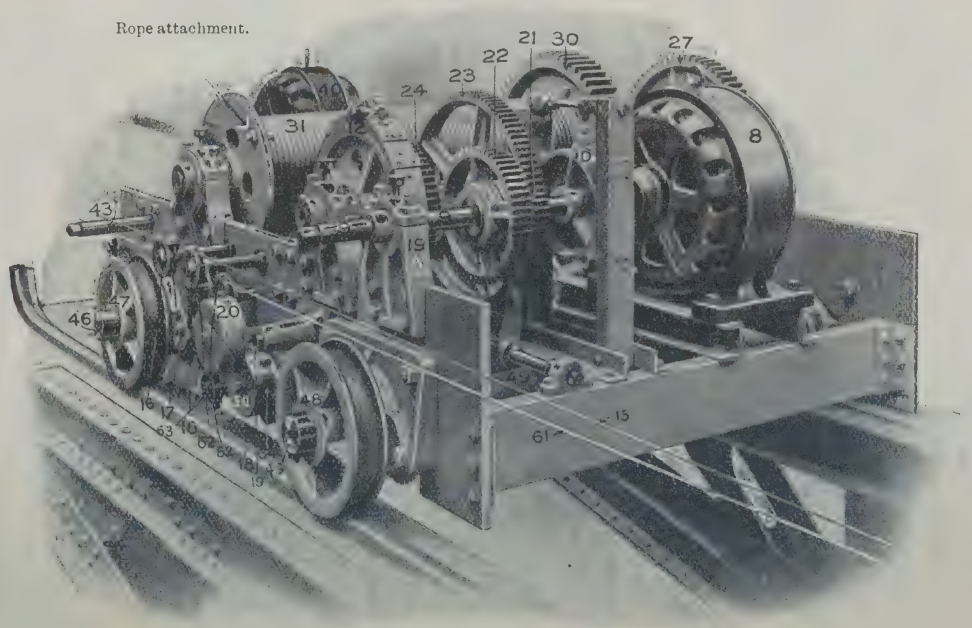

FIG. 3.—View of left-hand side of Babcock & Wilcox Crab, from hoisting motor end.

return sheaves of the hoisting ropes. The hoisting motor (8) is fitted with an extension shaft (9) on which is fixed the automatic magnetic brake (10). Two blocks press against the face of the brake pulley by means of a counterweight (50), when the crane is standing. When current is switched on, the weight is lifted by the action of the solenoid, and is automatically reapplied when current is cut off. There is also a mechanical brake (12), operated from the cage by a foot pedal attached to a lever. This lever is connected to the flexible wire (15) stretching from end to end of the cross-girders and passing over two fixed pulleys (16) and under a movable pulley (17) coupled to a counterweight (20) which serves to keep the brake strap clear of the brake-wheel. By operating the pedal the brake strap can be tightened round the brake-wheel.

The hoisting motor extension shaft (9) carries two sliding pinions, one for slow and heavy hoists (21), and the other for quick and light hoists (22), and these may be put into gear by means of a lever operated by hand from the driver's cage when the crab is opposite to it. These pinions gear with spur wheels (23) and (24) on the first motion shaft which carries the mechanical brake (12). At the farther end of this shaft, a pinion gears into the spur wheel (27) on the second motion shaft. On this latter shaft, another pinion gears with the main spur wheel (30) which is bolted to the hoisting barrel (31). The two ends of the hoisting rope are secured to the ends of this barrel, which is grooved right and left-handed, so that the rope on each side is wound uniformly towards the centre and a truly vertical movement given to the lifting hook. An overwinding gear is fitted consisting of a screw spindle and travelling nut which, when the hoisting hook has reached its highest position, strikes a lever connected to an emergency cut-out in series with the hoisting controller and motor. This action opens the switch, cuts the current off the motor and applies the magnetic brake, thus stopping any further winding. With D.C. motors the hoisting controller is fitted with rheostatic brake steps to control the load when lowering. With A.C. motors hand gear is used to release the magnetic brake mechanically. This gear consists of a lever attached to a flexible wire (61), stretching from one end to the other of the cross-girder, passing over two fixed pulleys (62) and under a movable pulley (63), fitted with the counterweight (50). By operating the lever, the movable pulley and weight may be raised, thereby freeing the brake to any desired extent.

On the spindle of the traversing motor (40) a pinion is fitted which gears with a spur wheel keyed on to the first motion traversing shaft (43). By means of another pinion and spur wheel this shaft is connected to the driving axle (46) to which are keyed two of the wheels (47) on which the crab runs. The remaining two wheels (48) are keyed to the trailing axle (49) which runs freely in its bearings.

For handling hot ingots in rolling mills, special cranes with semi-automatic tongs are used, and have been made to fulfil such varied functions as stripping the ingot from the mould, charging and withdrawing the ingot from the soaking pit, and lifting and replacing the soaking pit cover.

For handling molten metal, special cranes known as 'ladle cranes' have been designed, and are made up to 150 tons capacity, but cranes of 80 to 100 tons are more generally used. These cranes are fitted with two crabs, the main crab running on top of the girders and the auxiliary crab between the girders and on the lower flanges. The main crab has two barrels arranged so that the hoisting ropes pass outside the girders to sheaves attached to a lifting beam from which the ladle is suspended. The auxiliary crab has usually a lifting capacity of about 20 per cent. of the main crab and serves for general lifts and for tipping the ladle if required.

For handling forgings under hydraulic presses, special cranes have been developed with relieving gear to prevent overloads due to the action of the press in pulling down a forging which is suspended not quite level with the anvil. These cranes are made up to 200 tons capacity, and can be fitted with detachable gear for rotating the forgings.

For stores, warehouses, and machine shops an overhead travelling crane with underhung jib has many advantages owing to the increased area covered by the jib.

For outside service the Goliath crane fulfils the same function as an overhead traveller, and eliminates the gantry. Fig. 2 (p. 804) shows a crane of this type designed for lifting loads up to 200 tons.

The speeds of working and sizes of motors are:—

Hoisting, slow gear	200 tons,	3 ft. per min.	Motor 65 h.p.
,, fast ,,	75 ,,	8 ft. ,,	
Traversing	200 ,,	30 ft. ,,	,, 25 ,,
Travelling	200 ,,	50 ft. ,,	,, 65 ,,

The load is lifted on sixteen parts wire rope, winding one part on to each of two barrels rotated by the 65 h.p. motor through four reductions of gearing. Change-speed gear is provided for handling loads up to 75 tons at a quicker speed. An automatic solenoid and automatic mechanical brake are fitted, the latter working entirely enclosed in an oil box. The crab is mounted on four two-wheeled bogies and traversed by the 25 h.p. motor driving four rail wheels through four reductions of gearing. The crane travels on a twin rail track, there being eight centre-flanged steel-tyred wheels under each leg. Four wheels on each side of the crane are driven. The girders are of the lattice type with auxiliary girders and bracing to give lateral stiffness. All motions are operated from an enclosed cabin situated in an elevated position, the hoisting and travelling controllers are of the contactor type and the traversing of the drum type.

Overhead Runways.

Overhead runway systems, consisting of a track formed from a single rolled-steel joist which may be curved to suit local conditions, and have switches or turntables, are frequently installed in warehouses, steelworks, gas works, and other situations where an overhead crane is unsuitable or too expensive. Hand-pulley blocks and trolleys are used on the runways for occasional service and light loads, but for speed and loads up to five tons an electric trolley hoist should be installed. These may be either floor or cage controlled, and have usually separate motors for hoisting and travelling. The lifting speed may be as much as 100 ft. per minute, and the travelling speed from 200 to 800 ft. per minute, according to the duty required.

Grabs can be fitted to lift coal, ore, or similar material.

Derrick Cranes.

The Scotch derrick crane, largely used by contractors, has many advantages on account of its portability, simplicity of erection and long outreach. As commercially manufactured in stock patterns, these cranes have not usually a very large factor of safety, and if the full load is to be constantly handled it is advisable to specify a crane for about 25 per cent. greater load. The B.E.S.A. has drawn up Specification No. 327, 1928, as a guide on details of construction of these cranes with a view to securing a uniform design and factor of safety. Timber is prohibited as a stress-bearing material. Cranes of this type are specially made in large sizes for dock-side service in fitting out vessels under construction, but are giving way in favour of the more efficient cantilever crane.

British Standard Specification for Derrick Cranes.

(No. 327—1928.) (*Extract.*) *

Applies to the 'Scotch Derrick' or 'Stiff Legged,' 'Guy Derrick,' and 'Power Derrick,' types of cranes used in building operations.

Appendix III. of the Specification gives the following :

List of British Standard Specifications for Materials to be used in Manufacture of Crane Details.

Crane Detail.	British Standard Specification.	Crane Detail.	British Standard Specification.
Drums and iron castings . . .	No. 321.	Ropes . . .	No. 302.
Steel castings (both general and gearing)	No. 24, Specification No. 10, Class A.	Rivets . . .	No. 15, Grade A.
Hooks . . .	Best — Yorkshire Wrought Iron No. 51, or Mild Steel No. 24, Specification No. 8, Class B.	Rotating and fixed shafts . .	No. 24, Specification No. 8, Class B.
Shackles . .	Do. do. do.	Screw threads .	No. 92.
Turnbuckles . .	No. 24, Specification No. 8, Class B.	Ties and bridles .	Grade A Wrought Iron, No. 51. Mild Steel, No. 15, Grade A, Galvanised Steel Wire Rope with steel eyes.

Keys . . .	No. 46.	Paint . . .	No. 262.

Locomotive Cranes.

For general service on railway sidings around works and shipyards the locomotive steam crane is unequalled. These cranes are made in standard sizes up to 10 tons capacity and lift the load free on track with the jib in any position.

* By permission of the British Engineering Standards Association.

The following table gives particulars of standard steam cranes :—

STANDARD LOCOMOTIVE STEAM CRANES, 4 FT. 8½ IN. GAUGE.

Size.	Radius.	Size of Engines. (Cylinders.)	Size of Boiler.	Steam Press.	Speeds.			Weight.
					Hoist, f.p.m.	Slew, r.p.m.	Travel, f.p.m.	
Tons.	Ft.	Ins. Ins.	Ft. Ins. Ft. Ins.	Lbs.				Tons.
3	16	7 by 10	7 9 by 3 6	100	80	2½	350	14½
5	16	8 by 10	8 3 by 4 0	100	80	2½	350	22½
7	16	8 by 12	8 3 by 4 0	100	50	2	300	32½
10	16	9 by 12	9 0 by 4 0	100	40	2	250	45
15	16	9 by 12	9 0 by 4 0	100	40	1½	200	54

For cranes of longer radius or greater lifting capacity than the above, blocking girders and rail clips are fitted to give the necessary stability, or the cranes may be made heavier.

Cranes that are to travel round sharp curves should have sliding axle gears or differential gears and the conditions pointed out to the crane makers at the time of ordering.

The travelling gear should be of steel, also the slewing ring and pinion.

The slewing spur-ring forms the roller path and should rest on a machined seating on the truck, the pressure of the slewing rollers being sufficient to hold it in position for normal working, but in the event of sudden loads it will slide sufficiently to absorb the shock and prevent damage to the gearing.

The engines are usually of the double cylinder non-condensing type, cranks at right angles and cut off at about three-quarter stroke. The boiler is of the vertical cross-tube type for a working pressure of 80 to 100 lbs. per sq. in. and should be lagged. Two means of feed should be fitted, and the incoming water should enter above the firebox and not impinge directly on the heated plates.

The mountings should preferably be flanged, and secured by studs to pads riveted to the shell of the boiler, rather than screwed directly to the shell. The safety valve should be separate and not a combined mounting with the stop valve.

A list of standard boiler mountings would consist of

1 steam-pressure gauge with syphon ;
1 water gauge with plate glass protection ;
1 spring loaded safety valve ;
1 steam stop valve ;
1 injector with steam cock and feed check valve ;
2 test cocks ;
1 steam jet cock and pipe to funnel ;
1 blow-off cock.

The feed pump may be either a steam donkey pump or be driven direct from the engine crosshead.

RUNABOUT CRANES.

For service in situations where overhead cranes or rail tracks are not available, a handy type of crane, known as the Runabout Crane, has been recently developed. It is operated by electric motors, taking current from storage batteries or a petrol-driven dynamo. The truck or chassis carries the source of power, the operating motors, and gearing. It is mounted on a fixed two-wheel axle, and at the rear on a two-wheel articulated castor which adapts itself to any unevenness of the ground and is used as the medium for steering and slewing. The jib is of the bascule type, pivoted at the apex of an A frame carried on the chassis. It is held and adjusted by a wire rope purchase acting on the back arm operated through derricking gear to vary the height and radius. The load is lifted on wire rope and held by an automatic solenoid brake. The cranes are made in sizes up to 2 tons at 6 ft. outreach and 25 cwts. at 10 ft. 6 ins. outreach, in front of the truck.

STEAM BREAKDOWN CRANES

for use on the permanent way, have been made up to 100 tons lifting capacity, but in Great Britain the usual size is from 10 to 35 tons. The truck of these cranes is provided with the usual permanent-way fittings and the axles are spring borne. The maximum load per axle with the crane in running order should not exceed 18 tons. When the crane is 'in train' the travelling gear should be disconnected and the superstructure locked to prevent it turning. Owing to the limited space due to the crane having to clear the loading gauge, a comparatively small size boiler must be fitted, and this should be of the multitubular type as the ordinary cross-tube boiler would not generate enough steam.

Wharf Cranes.

For dockside service in loading and unloading ships, the high gantry type of jib crane is principally used. The usual sizes are from 1½ tons to 5 tons and the radius from 40 to 60 ft. The gantry is made wide and high enough to admit of the passage of rolling stock underneath and to keep the jib clear of the sides of large vessels. A separate motor should be fitted for each motion.

Typical speeds of working, in feet per minute, are as follows :—

Description.	Size.		
	1½ tons.	3 tons.	5 tons.
Hoisting	200	150	120
Slewing	500	400	300
Travelling	100	100	80
Derricking	150	120	100

For high derricking speeds some form of compensating gear is essential to reduce the power consumption due to raising the load and jib each time the radius is reduced. With the ideal compensating gear the path of the load is kept horizontal as the jib is raised or lowered, and with the jib balanced the power required is only that necessary to overcome friction.

Numerous types of compensating gear have been invented during the past few years, some of which are very complicated, and the crane user should select those of the simplest construction with the minimum number of moving parts, and pay special attention to the lead of the hoisting rope, which often suffers considerably through being passed round numerous pulleys in order to give the desired level path to the hook as the jib is raised or lowered.

Luffing motion operated by a crank is often advocated, as the throw of the crank restricts the movement of the jib between the maximum and minimum radius; but in practice this is no real advantage as limit switches must be fitted as on rope-operated gear, otherwise the reversal of movement caused by the crank, irrespective of the direction of rotation of the motor, prevents the driver from knowing in what direction to start the motor to produce the required movement of the jib.

For rapid handling of coal, ore, or similar loose materials, the transporter grab crane is unequalled. The load is carried by a trolley which travels on a horizontal track, supported in a suitable manner by the crane structure, which latter may take the form of a tower with cantilevers on each side or a bridge, if it is desired, to convey the load over a considerable distance.

If working at the dockside the outer cantilever may be made to hinge up to clear the masts and funnels of ships when coming alongside.

The operating machinery can be fixed on the structure and the trolley carry only guide sheaves for the hoisting ropes and be hauled along by other ropes winding on to a separate winch, or the hoisting and transporting gear can be carried by the trolley. The latter system is usually adopted when the gross load exceeds 5 tons, as with the fixed machinery system the wear of the ropes becomes excessive in the larger sizes and off-sets the initial saving due to the lighter design of structure.

The advantage of this type of crane over the jib crane is that the load is conveyed in a direct line from point to point instead of through the arc of a circle. The transporting speed can be at the rate of 800 to 1,000 ft. per minute, whilst the maximum safe slewing speed is not more than 400 to 500 ft. per minute. With a 3-ton grab the transporter crane will usually handle 150 tons per hour against 100 to 120 tons on a jib crane.

On the larger types the driver travels with the trolley and is always immediately above the area of operations. In some cases the trolley is fitted with a revolving jib of about 10 ft. radius, from the point of which the grab is suspended. This enables the driver to cover the whole area of the ship's hatchway without moving the main structure, resulting in a speeding up of operations.

For handling coal, ore, and similar materials, much time and labour is saved by using grabs; these may be on the single or double-chain principle.

The single-chain grab may be fitted to any crane lifting on a single fall of rope, but grabs of the double-chain type require an extra drum to coil up the opening or closing rope. This should preferably be driven through a friction drive, although for short lifts a spring drum is quite suitable.

With the larger sizes two independent motor-driven winches, one for each rope, are sometimes used. The opening and closing of the grab is then performed by movement of the motor controller handles. For satisfactory operation automatic contactor controllers should be used with relays to prevent excessive overloading of the hoisting motor in the event of the driver being late in starting the holding rope winch when coming away from the material with a full grab.

Grabbing work is very severe on cranes, and the nominal size of the crane should be 50 per cent. in excess of the combined weight of grab and contents. The empty grab may be balanced by sliding counter weights to reduce the power consumption.

Double rope grabs have a tendency to spin and twist the ropes round each other. This may be overcome by fitting a large sheave at the grab head, and leading the opening and closing rope back to the jib head or winch, the grab being thus suspended on three ropes spread apart by the sheaves, which keeps it perfectly steady. On heavy grabs two hoisting ropes are used either on the single or double chain principle.

Automatic self-dumping single-rope grabs, which open when the weight of the grab is relieved from the hoisting rope, require only a single-drum winch for operation and give a higher duty than the single-rope grab with fixed discharge gear.

SHIPBUILDING CRANES.

For service over shipbuilding berths, high gantries with overhead travellers and mono-rail cranes, gantries with cantilever cranes, steel derricks and tower cranes, are used, and experience favours the latter type.

Tower cranes may be either of the fixed or travelling type, practice in Great Britain being inclined to the fixed type, as they require less clearance between the berths, and use is made of valuable space which would otherwise have to be kept clear for the track of a travelling crane.

The crane structure consists of a horizontal cantilever supporting the track for the load trolley, and is carried on the top of a braced steel mast which is free to revolve inside a fixed or travelling tower. The cantilever is balanced by a tail carrying the machinery, which gives the crane a hammer-headed appearance.

The motions of hoisting, slewing, racking, and travelling are fitted, operated by independent motors. The cranes are made with a lifting height up to 120 ft., and a radius up to 140 ft. The usual capacity is 5 tons at 100 ft. radius and 10 tons at 50 ft. Travelling cranes of this type have been made to lift 30 tons at 100 ft. radius, 15 tons at 140 ft. radius, and with a height of lift of 120 ft., but these are exceptional sizes.

These cranes, if desired to lift varying loads at different radii, should be fitted with an automatic anti-overload device which will prevent a load above the safe limit for its radius being lifted, and will also prevent the trolley traversing beyond the safe radius for that particular load.

For fitting out, cranes of the wharf type with derricking jibs are used, and range in size from 10 to 40 tons, with radii up to 80 ft., according to requirements. Two speeds of hoisting are generally arranged, so that light loads may be lifted at a speed of 50 to 80 ft. per minute. A typical crane of this type lifts 30 tons at 55 ft., 20 tons at 72 ft., 10 tons at 80 ft. radius, and is mounted on a gantry to clear rolling stock, the centres of the gantry track being 22 ft.

Cranes of this type are installed for dry dock service, and it is occasionally necessary that they should work from both sides of the dock. This may be arranged by connecting the two sides of the dock by a track at the end and introducing turntables, or better by making the track sweep round on a curve and carrying the rail wheels on special swivelling bogies and inserting an epicyclic gear between the sections of the travelling motion cross shaft which connects the driving rail wheels on each side of the crane.

A large fitting-out crane is shown by fig. 4. This crane is designed to lift a load of 25 tons at 84 ft. radius, 5 tons at 112 ft. radius, and has a total range of lift above track level of 137 ft. The centres of the track rails are 40 ft.

The load of 25 tons is lifted at a speed of 20 ft. per minute, and 5 tons at 100 ft. per minute.

Floating cranes are occasionally used for fitting out and repair service, and have the advantage of being transferable from dock to dock, but with them it is not easy to deposit a heavy load with

precision, as the crane follows the movement of the water and its equilibrium is disturbed with every fluctuation of loading. These cranes are usually steam operated, but in recent years several large cranes have been electrically driven. This appears an unnecessary and expensive refinement, offering little advantage to compare with the additional cost of installing generators unless other use can be made of the power.

The pontoons are usually rectangular, flat-bottomed vessels, but if self-propelled it is advisable to give them a ship shape. The angle of heel under full load conditions and a 5 lb. wind should be not more than 5°. Travelling ballast is sometimes fitted to limit the heel under various loading conditions. A crane of this type, constructed by Sir Wm. Arrol & Co. Ltd., Glasgow, for the Brazilian Government, is designed to lift 30 tons at 10 metres outreach from the side of the vessel and is steam operated, the motions of hoisting, derricking, and slewing being fitted.

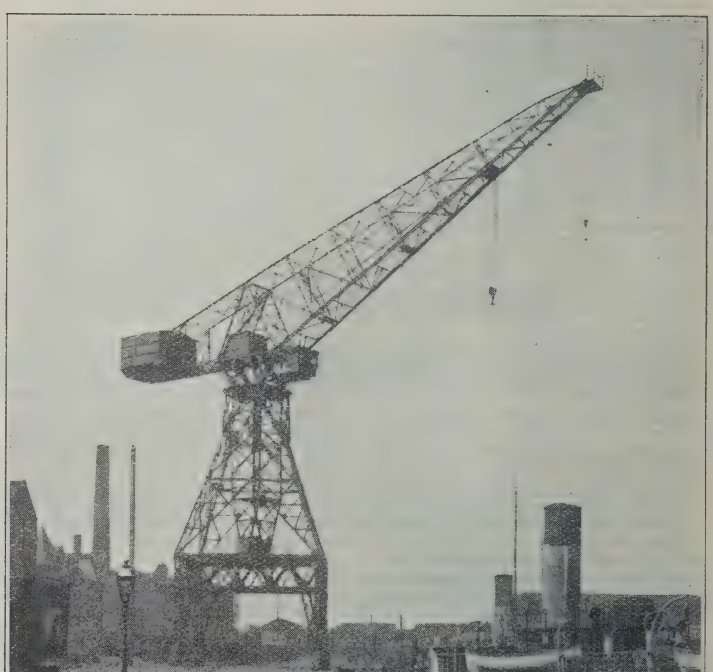

FIG. 4.—25-Ton Wharf Crane.

The pontoon, built by Messrs. Ritchie, Graham & Milne, of Glasgow, is of the self-propelled type, 150 ft. long by 50 ft. beam by 8 ft. deep, and is fitted with two sets of compound surface condensing engines having cylinders 13 ins. and 26 ins. by 18 ins. stroke, to give a speed of seven knots.

The outline of the largest floating crane so far constructed is shown in fig. 6, p. 814. This crane is designed to lift 350 tons at a radius of 100 ft., 300 tons at 121 ft., and 50 tons at about 160 ft. The range of lift with full load is 140 ft., and with 50-ton load 200 ft.

The crane, which was made by Messrs. Cowans, Sheldon & Co., Ltd., of Carlisle, for service in Japan, is operated by steam, there being nine sets of double-cylinder condensing engines, each motion being independently operated without the use of clutches. Control of the load for lowering is obtained by hydraulic brakes which enable very precise movements to be obtained.

The pontoon is 270 ft. long by 92 ft. wide, with draught of 10 ft., and is self-propelled by twin-screw compound engines supplied with steam at 150 lbs. pressure from two single-ended boilers.

The boilers are of the water-tube type and supply steam to the crane engines, auxiliary machinery and electric light set.

The Giant cantilever crane is adapted for loads from 75 to 250 tons and enables large portions of machinery, gun turrets, etc., to be lifted on board as a complete unit. A typical crane of this

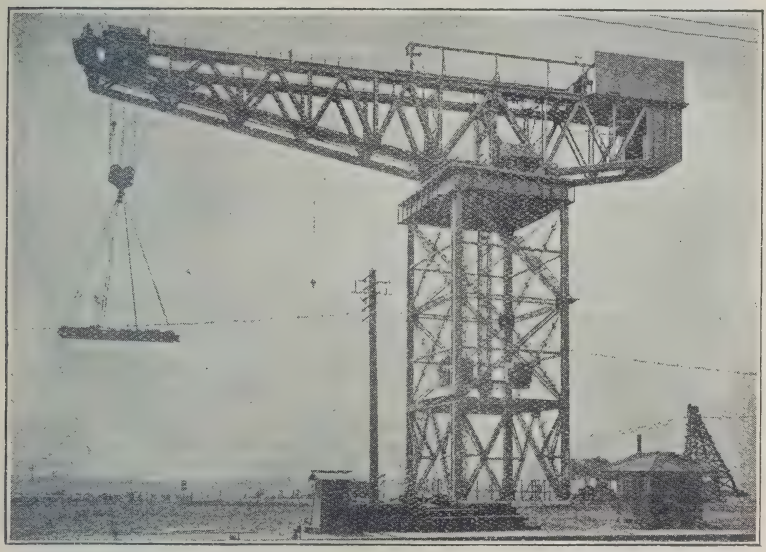

FIG. 5.—250-Ton Giant Crane.

type, manufactured by Sir Wm. Arrol & Co. Ltd., Glasgow, is shown in fig. 5. The leading dimensions are :—

Max. radius for 250 tons	105 ft.
,, ,, ,, 120 ,,	130 ft.
,, ,, ,, 80 ,,	160 ft.
Height to top of tower	140 ft.
Base of tower	50 ft. square.

The main hoisting machinery consists of independent hoists each of 125 tons capacity, which can be worked together when required. The auxiliary hoist is of 40 tons capacity and the jigger hoist of 10 tons, this latter having a separate track and trolley on the underside of one of the cantilever girders. The crane was satisfactorily tested with a load of 360 tons.

CAPSTANS.

For hauling trucks in goods stations or on the dock side a capstan designed to exert a pull of 1 ton at a speed of 150 to 200 ft. per minute is sufficient. The free bollard type with the rope attached to the bollard is more economical in use than the fixed bollard type which depends upon the friction of the coils of rope round the bollard for hauling power.

The warping of ships into position in the docks is done by capstans of from 10 to 20 tons pull. A constant torque at varying speeds is the desideratum for this duty, and the characteristics of the Austin constant-current motor make it eminently suitable for this work.

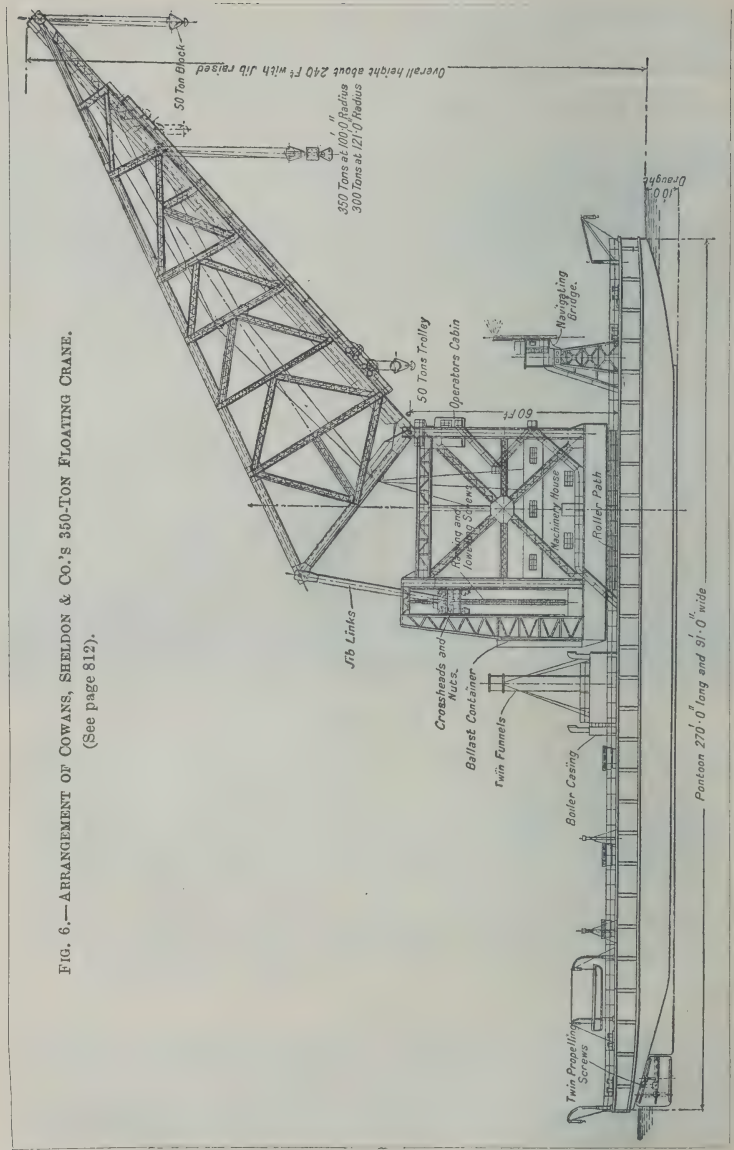

FIG. 6.—ARRANGEMENT OF COWANS, SHELDON & CO.'S 350-TON FLOATING CRANE.

(See page 812).

General Data.

Structures.

Crane structures should be made of open-hearth mild steel, 28 to 32 tons tensile strength, extension not less than 20 per cent. in eight inches. In determining the section of members, allowance should be made for the vibration due to the movement of the load and machinery, for the movement of the structure in the case of a travelling crane, and deflection should be considered where bearings for shafts are carried on structural members. The stresses should be such as to give a factor of 5 to 6 on the ultimate strength of the material. The ratio of length to radius of gyration should carefully be considered in struts, and charts plotted from Claxton Fidler's or Tetmeyer's formula form a reliable basis on which to determine the stresses. For wind bracings the factor of safety need not be more than three, as this is an exceptional loading infrequently applied.

Wind pressure on cranes in exposed positions in Great Britain may be taken as a maximum of 40 lbs. per sq. ft. It is inadvisable to work a crane in a wind pressure above 5 lbs. per sq. ft., and when designing the structure it is therefore unnecessary to allow for a higher pressure under full load conditions. The maximum wind pressure must of course be considered separately.

The revolving superstructure of jib or cantilever cranes may be carried on a ring of live rollers, or on a set of four or eight large diameter rollers designed as travelling wheels, but with conical treads and unflanged. The live rollers may be of either forged or cast steel and should run between two steel guard rings connected to the centre pin casting by radial rods. A gunmetal washer should be fitted between each roller and the outer guard ring, to take the outward thrust of the rollers. For unhardened rollers the pressure in lbs. should not exceed 400 by length in inches by diameter in inches. The roller-paths should be of steel, machined conical on the face to form a full bearing for the rollers.

On jib cranes up to about 5 tons capacity the roller-path frequently consists of a flat-bottom rail bent to a circle, and the superstructure is then mounted on four rollers 15 ins. to 18 ins. diameter. This is a cheap and serviceable construction.

A friction clutch should be incorporated in the slewing gear adjusted to slip and prevent damage in the event of excessive shock due to too sudden application of the brake or the fouling of jib with some stationary object.

Gearing.

On all high-class crane work the gearing should be machine cut. For hand and low-power cranes cast-iron wheels and steel pinions are satisfactory, but for all high-speed cranes the gearing should be of steel, with the possible exception of motor pinions, which, to ensure silent running, may be of rawhide, fabroil, or phosphor bronze.

For heavy loads and high speeds, machine-cut double helical gearing is very satisfactory, efficient, and silent.

The strength of spur gearing can be determined by the Lewis formula (page 915).

Gearing with stub teeth and 29° involute is advised for crane work, as the strength is greater than standard 14½° involute, by 30 per cent. with a rack, to 50 per cent. with a 12T pinion. The addendum is 0·27 of the circular pitch and the dedendum 0·32. With diametral pitch the outside diameter of the wheel is determined by adding 1·75 to the number of teeth and dividing by the pitch.

Worm wheels should consist of a phosphor bronze rim fixed on a cast-iron or steel centre, and have machine-cut teeth. The worm should be of high tensile forged steel and need not be hardened unless facilities exist for grinding the threads. In determining the size of worm gearing the heating effect must be considered as well as the strength.

For the highest efficiency a special globoidal gear, known as Enveloping Worm Gear, developed by Bostock & Bramley of Leeds, is recommended. This gear has a greater bearing surface than any other form and occupies less space than ordinary worm gear for the same power.

(See also 'Worm Gearing,' p. 937).

Shafts.

In designing shafts the resultant loads should be determined and the effect of combined bending and twisting moments considered. The equivalent twisting moment due to combined bending and twisting is equal to

$$BM + \sqrt{(BM)^2 + (TM)^2},$$

where,

BM = bending moment; TM = twisting moment.

Stresses should be low on account of the frequent reversal and impulsive loads common with crane work. Where keys are fitted, the shafts should be increased in diameter.

Bearings.

For cheap hand cranes the bearings are usually of cast-iron and not bushed. All power-driven cranes should have gunmetal bushed bearings. The bearing brackets should be fitted with caps, and the bushes be in halves. Studs for securing the caps are not desirable.

Tee-headed bolts should be used, and these should fit in a slot accessible from the outside of the pedestal, so that the bolts can be withdrawn after the cap is removed and without disturbing the steps. The pressure per sq. in. for shafts running at medium speeds should not exceed 600 lbs. For slow-moving pulleys and axles the pressure may be as high as 1,000 lbs. per sq. in. Fast-running shafts, such as motor spindles, should have ring lubrication. Axles are frequently fitted with float lubrication, which consists of a cylinder of cork floating in an oil-well formed in the inverted cap of the bearing and by contact with the axle supplying the necessary lubricant. Screw-down and spring-feed lubricators with grease are very satisfactory.

To reduce frictional losses, ball or roller bearings are sometimes fitted, and the makers should be consulted regarding the size of these. Ball bearings are very serviceable for worm thrust bearings, footstep bearings, and for under the hook.

Ropes.

Ropes for crane work should be of best plough steel quality, 6/37 stranding if above 1¾ in. circumference, below this size 6/24 or 6/19 stranding. For ordinary work a hemp core is suitable, but where exposed to heat a soft iron core is desirable. The diameter of the barrel and pulleys round which the rope passes should be between six to seven times the circumference of the rope. For high speeds it is advisable to use even larger pulleys than given by this rule. Sharp and reverse bends should be avoided, although with single ropes which may twist in winding the effect of a reverse bend is problematical. When lifting on a single fall, a so-called 'non-twisting' rope should be used. Ropes made from very high tensile steel wire are stiff and tend to 'bird-cage' or open out. The rope, particulars of which are given on page 828, is recommended for cranes. Ropes should be lubricated and examined in service for broken wires and corrosion. The barrels and pulleys should be machine-grooved to form a smooth and even surface for the rope to bed on. Hoisting ropes should have a factor of safety of at least seven, and even higher with small size ropes.

British Standard Specification for Round Strand Steel Wire Ropes for Cranes.*

(No. 302—1927.) (*Abstract.*)

(*This Specification is intended to provide for round strand ropes of Ordinary Lay having wires approximately uniform in diameter and of* 4 × 37, 6 × 19, 6 × 24, 6 × 37, *and* 6 × 61 *constructions, for the Lifting and Derricking, Ropes of Cranes and Coal Hoists, Transporters, and other similar lifting appliances.*)

3. The wire used in the manufacture of ropes to this specification shall be made from steel billets made by the acid open-hearth process and containing not more than 0·04 per cent. of sulphur and 0·04 per cent. of phosphorus.

The wire shall be of one of the following qualities as specified by the purchaser:

Grade A.—Special acid or 'Swedish' quality.

B.—Acid quality.

4. The wire used in the manufacture of ropes to this specification shall conform to one of the following descriptions, as specified by the purchaser:

Tensile Breaking Strength in Tons per sq. in.	Trade Description.
80– 90	Best Patent Steel.
90–100	Special Improved Patent Steel.
100–110	Best Plough Steel.
110–120	Special Improved Plough Steel.
115–125	Extra Special Improved Plough Steel.

14. The fibre used for the central or main core of the rope shall be new, and free, long fibre, good quality hemp, manila or jute.

(See also page 199.)

Hooks.

Fig. 7 gives proportions of hooks in terms of the diameter at the bottom of the thread. The size for any load can be arrived at by fixing the size of the shank to carry the load in tension. The area at the bottom of the thread must be taken. Hooks should be forged from mild steel.

Crane hooks depending from large travelling cranes in machine shops ought to be painted white, so as to be easily seen. With this improvement in visibility workmen will be less likely to run against a hook or to be struck by one which is moving.

Foundry ladle hooks fail from time to time without any previous indication of weakening, so that in many foundries it is usual to change them after a definite period of service. A German firm has brought out an improved hook made of a number of laminæ with an air space between.

* By permission of The British Engineering Standards Association.

This hook is said to be absolutely safe, for if a lamina should break, the remaining ones will be strong enough to hold the ladle. It is also necessary to replace only the broken strip. To ensure

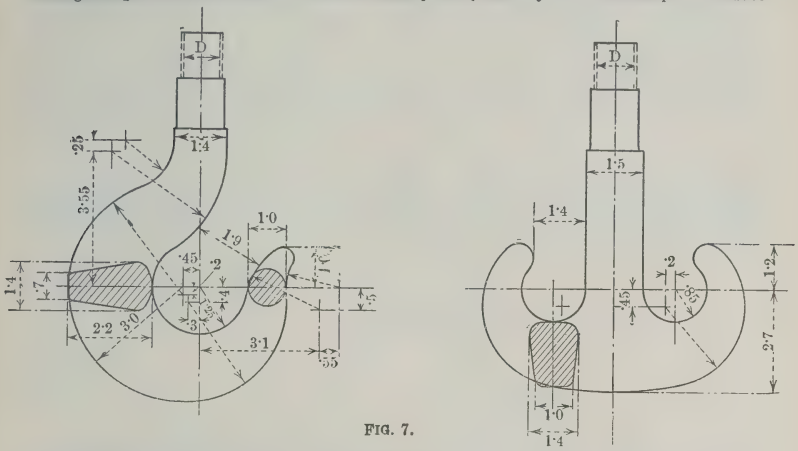

FIG. 7.

uniform wear, even when the load is at an angle, the jaws of the hook may be furnished with a two-piece bronze or steel roller bearing.

CHAINS.

Chains should only be used for grabs or situations where the fine strands of a rope would be damaged by abrasion. The working load for a welded iron chain is given by the rule.

$$W = \frac{(\text{dia. of iron in } \tfrac{1}{8} \text{ in.})^2}{9}.$$

Weldless steel chains are about 13 per cent. stronger, and make good slings on account of their lower weight. Steel plate driving chains are sometimes used for drives instead of gearing, and give good results if properly designed. The burden chain for large ingot rotating gears is best constructed of one inner and two outer links connected by steel studs.

(See also page 193.)

DESIGN OF LIFTING TACKLE.

Fig. 8 shows a faulty design of eye-bolt, likely to break without warning; and fig. 9 one which would stand rough usage, permit a pull at bad angles, and give notice before it broke, and at the same time possesses a useful strength (over 200 per cent.) beyond that of fig. 8.

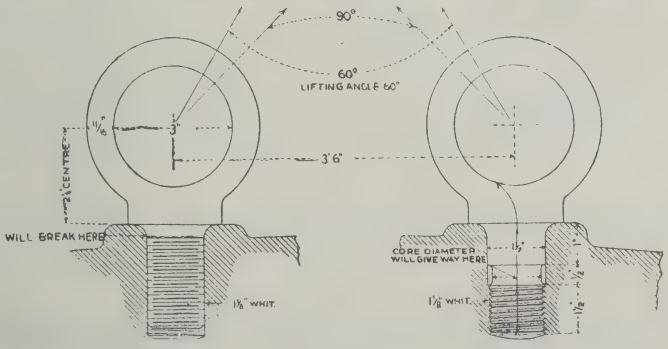

FIG. 8. FIG. 9.

These eye-bolts—hand-forged, of both types—have been tested to complete destruction at various 'punishing' angles, by Messrs. Kirkaldy, and the verdict has been from 50 per cent. to 250 per cent. in favour of the fig. 9 pattern.

The arrows depict the form and direction of the strains, and such were precisely followed in the tests by Messrs. Kirkaldy.

The increased strength, as a result of decreased material, refers to the reduced part A, for this reduction is an effective factor which contributes to the need that the strain of the load should be distributed over as large a volume of the composition of the bolt as is possible.

(*J. T. Towlson, 'The Electrical Review.'*)

Brakes.

One of the most important features on a crane is the brake, and this should have a large factor of safety. The brakes in common use are electric, automatic solenoid, centrifugal, automatic mechanical, and manual brakes. Hydraulic and pneumatic brakes are used for heavy loads, or where extremely fine control is desired.

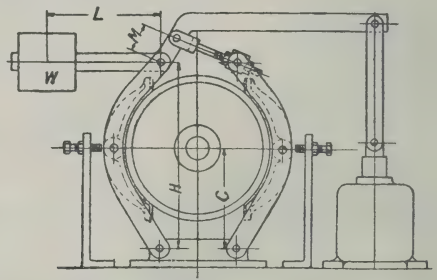

Fig. 10.

A typical arrangement of a solenoid brake is shown in fig. 10. The brake is applied by the weight and released by a solenoid magnet connected in the motor circuit so that it is excited immediately current is switched on to the motor.

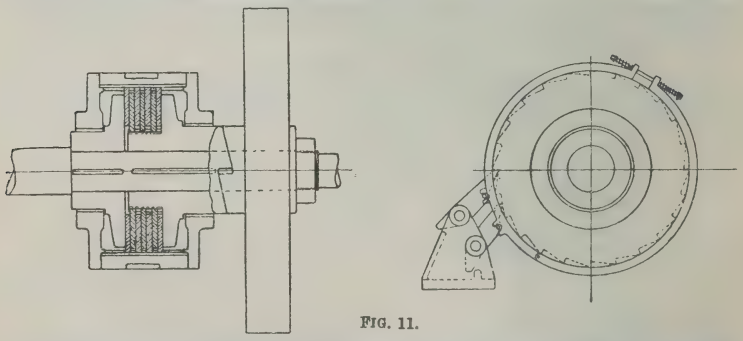

Fig. 11.

If F is the turning force on the rim and μ the coefficient of friction between the brake shoes and sheave, then the weight required to apply the brake equals

$$\frac{C \times M \times F}{H \times L \times 2\mu}$$

where C, M, H, and L refer to the dimensions shown in fig. 10.

The weight of the solenoid plunger and levers must be taken into account, and about 10 per cent. is usually added for friction in joints.

The centrifugal brake is designed to control speed, and does not serve to sustain the load at rest. In one form it consists of a series of weighted slippers which are pressed by centrifugal action on the inner rim of a fixed annulus, and thus have a retarding effect. The brake shoes should be slightly lubricated and ample radiating surface allowed to dissipate the heat generated.

The automatic mechanical brake, known also as the 'Weston washer brake,' depends for its action upon the friction between a set of fixed and rotating discs. The pressure on the discs is obtained by a screw and nut, or two helical surfaces which set up an axial thrust along the brake shaft. Fig. 11 shows one type of this brake in which the friction discs, alternately of bronze and steel, are enclosed in a cast-iron box, with ratchet teeth on the outside. One set of discs is connected by feathers to the box, and the other set to the thrust plate. The driving wheel has a helical face formed on the boss which engages with a corresponding face on the thrust plate. When hoisting, the discs are pressed up tight and the whole brake revolves, but when lowering, the pawls engage with the ratchet box, and hold it stationary. The pressure on the discs is relieved by the reversal of the motor, and the load is free to descend. As it tends to accelerate and gain on the motor, the discs are pressed together again and the friction between the surfaces of the fixed and revolving discs forms the braking effect. Ample lubrication and radiating surface are essential for the successful operation of this brake.

The pitch of the helical faces is determined by the following formula:

$$T = \frac{PL}{R \times \mu \times N'} \quad \text{and} \quad \frac{PL}{Tr} - f = \tan A;$$

therefore,

$$\text{lead of helix} = \tan A \times 2\pi r;$$

where,

R = average radius of disc;	μ = coefficient of friction = ·07;
PL = torque on driving wheel;	r = mean radius of helical faces;
A = angle of helix;	T = thrust or pressure on discs;
N = number of rubbing surfaces;	f = coefficient of friction of helical faces.

The brake should be proportioned so that an angle of helix of about 10° will give the requisite pressure. The brake should run at a speed not exceeding 150 revs. per minute, and the pressure on the discs should not be more than 200 lbs. per sq. in. and on the helical faces 500 lbs. per sq. in.

Manual brakes are usually of the band or post type. Band brakes should have a bar fitted round the outside of the strap with adjusting screws to ensure that when the brake is released the strap will come away evenly from the sheave.

Band brakes are generally only suitable for a torque in one direction, i.e. away from the fixed end of the strap.

To find the pull to be applied to the loose end of the strap, the following formula may be used:

$$P = \frac{F}{e^{\mu\theta} - 1},$$

where,

P = pull;	μ = coefficient of friction;
F = turning force on rim of brake sheave;	θ = angle of sheave embraced by strap in radians.
e = base of Napierian logs.	

Brake sheaves are usually made of cast iron, but steel should be used for severe duty. The brake shoes or strap may be lined with wood, leather, or one of the asbestos fabrics such as 'Chekko' or Ferodo lining; wood and leather are inclined to char and glaze and the coefficient of friction is reduced. Bonded asbestos (page 850) is not subject to these objections and maintains a constant coefficient of friction, which in practice may be taken as 0·3.

Electric cranes may be controlled by dynamic or rheostatic braking if direct current is used. Dynamic braking with potentiometer control is to be preferred to plain rheostatic braking, as practically automatic speed control is obtained in the lowering direction irrespective of the weight of the load. Heavy rushes of current and mechanical shock can be produced on the motor by either system of electric braking, and some form of current limit control should be provided.

Speeds up to 1½ times full load hoisting speed can now be obtained without difficulty in lowering the light hook under potentiometer control.

A shunt solenoid should be used with this system of braking, as the current may fall too low to excite a series coil sufficiently to hold off the brake.

Messrs. Laurence Scott have recently developed what is termed floating brake control for speed regulation, with the object of avoiding the disadvantages of dynamic braking. The brake consists of fixed and rotating discs mounted co-axial with the motor spindle. The discs are pressed together by springs and released by an electric magnet, excited when current is switched on to the motor. By arranging the starting resistance so as to divert current from the brake coils the magnetic flux is weakened to such a degree that the pressure of the springs begins partially to apply the brake and the speed is regulated according to the amount of current diverted from the series winding of the brake coils. The value of the resistance in circuit is adjusted through the medium of the controller used for starting the motor. This system has been used on a number of cranes with success.

To control the lowering of heavy loads at slow speeds, a hydraulic brake is the most efficient. In principle this consists of either a reciprocating or rotary pump with closed circuit and throttle valve.

The pump is in the train of gearing between the motor and the rope drum, and by means of a free wheel drive is inoperative in the hoisting direction. On lowering, the solenoid or other brake is released, and the descending load drives the gearing and pump. The speed is controlled by the throttle valve, and very fine regulation at constant speed can be obtained. The system is especially suitable for placing guns, turbines, and engines on board ship.

For gun tempering, armour treatment, and processes where immersion in a cooling bath is necessary, it is essential that the load should be rapidly lowered at speeds varying from 60 ft. to 150 ft. per min.

The lifting speed is about one-tenth of these speeds, and the usual practice is to disconnect the rope drum from the gearing and motor when lowering.

A coil clutch is used for the purpose, and a powerful brake must be fitted to control the lowering speed and sustain the load. Manual brakes have proved satisfactory for this purpose, particularly in conjunction with a centrifugal brake for speed control. On cranes of over 100 tons capacity elaborate electro-hydraulic systems have been used with great success, but they are very costly.

Electrical Equipment.

Cranes may be worked by either direct or alternating current, but the former is to be preferred for the following reasons :

1. Series-wound motors may be used with high starting torque and speed variation in proportion to load.

2. Very fine control can be obtained and dynamic braking used.

3. Less wiring than with slip-ring motors.

Alternating-current motors usually require less attention than direct-current motors, but the starting torque is limited and the running speed is practically the same under light and full load conditions. The starting torque for alternating-current motors should be not less than two-and-a-half times the full load torque, and in fixing the horse-power it is advisable to make it about 10 per cent. higher than for direct-current motors for the same duty.

With reference to paragraph 1, it should be noted that whilst with ordinary series motors the speed increases with a reduction in the load the variation is not very great between full and approximately half load, and as in many cases light loads are more frequently lifted, mechanical change gear is used to increase the speed and take advantage of the full power of the motor. This can, however, be eliminated by means of a special two-speed motor, designed to develop its full horse-power at two definite speeds besides having the usual series characteristic. The alteration in speed is obtained by diverting part of the field current, and with the Scott Bentley discriminator control this can be done automatically, thus relieving the operator from the trouble of changing gear and ensuring the correct speed for the weight of the load. The efficiency of the crane is increased without any added complications.

Two-speed squirrel-cage motors are now also manufactured, the change of speed being obtained by altering the number of poles.

The horse-power is in proportion to the speed, and the principal object of this design is to reduce the initial current peak by starting up at a slow speed and switching over to the higher when the gear is in motion.

Squirrel-cage motors are not in general suitable for crane work, although a number of cranes have been equipped with special squirrel-cage motors having high-resistance rotors and giving twice full load torque at starting. The starting current is about four to five times the full load current, and the switchgear should be of robust design. These motors are not suitable for a heavy duty or for where more than about 20 h.p. is required.

All motors should preferably be of the totally enclosed type. For ordinary engineering shop service crane motors rated to develop their full power for a period of half-an-hour with a tempera-

ture rise of 90° F. are quite suitable. For steel works and other situations where the duty is severe, the rating should be for one hour. It is desirable to have the yoke and bearings made in halves so that easy access may be had to the interior of the motor.

A special design of direct-current motor known as the Mill type is largely used on steelworks cranes. It has a steel carcase made to hinge open along the centre line to permit of easy removal of the armature. The armature is of small diameter to reduce inertia stresses on reversal, and the insulation and winding are such as to permit of stalling the motor without injury. It was originally developed for service in rolling mills, hence the name.

Controllers.

For ordinary crane service and motors up to about 60 h.p. the drum controller gives very good service. There should be ample room inside the controller for connections, all parts accessible, finger tips and drum contacts easily renewable, insulation of mica or micanite, and a definite step should be felt as the barrel is moved round to each contact. Magnetic blow-out should be fitted on direct-current controllers.

For frequent operation and large currents a solenoid operated or contactor controller should be fitted. The contactor switches handle the main current to the motor and are controlled by a small drum, or master controller, which deals only with the shunt current required to excite the contactor coils. A development of this system is the Holme Portable Remote Control, in which the master controller can be carried about by the operator and connection is made to the contactor panel by a multicore flexible cable.

Creeping control for foundry or riveting work is obtained by inserting resistance in parallel with the motor armature circuit, thus magnifying the strength of the field and enabling full-load torque to be obtained at a very slow speed.

Cam operated controllers have outwardly the appearance of drum controllers but the fingers consist of a series of simple contractors actuated by a number of cams mounted on a vertical spindle rotated by the controller handle. They are used where the current is considered rather heavy for an ordinary drum controller and yet not sufficiently heavy to justify an automatic controller.

On alternating current circuits speed regulation is obtained by resistance in the rotor circuit, but the same range of speeds cannot be obtained as with direct current, particularly on light loads.

When creeping speeds are required with alternating current the most practical method is to load up the motor with a manual brake, and then use the controller and resistance to adjust the speed.

Up to about five h.p. resistances are usually made of wire-wound porcelain bobbins, and above this power consist either of stamped steel grids or a drawn continuous strip bent into grid form. The grids should be well stiffened to eliminate vibration and sherardised to prevent rusting. Cast-iron grids should be avoided, as they give trouble due to breakage.

Resistances are usually rated to be in circuit two or five minutes out of every fifteen minutes, with a temperature rise not exceeding 350° to 400° F. For creeping control ten minutes or even continuous rating is desirable.

Switchboards.

Many cranes are fitted with a main switch and fuses for the protection of each motor circuit, but it is desirable that these should be replaced by a main automatic circuit breaker and relay switches for each branch circuit. The relay switches do away entirely with fuses and obviate the loss of valuable time at critical moments due to replacing them. Each switchboard should have a pilot lamp and socket for portable lamp connection. It is advisable, although not essential to fit an ammeter and a voltmeter.

Limit Switches.

Limit switches to prevent overwinding or overtravelling should be of the shunt type, and connected in the no-volt coil circuit of the main breaker on the switch-board, so that in the event of the switch coming into operation the main circuit is opened at the breaker.

Special contacts can be fitted on the controller to short-circuit the limit switch on bringing the controller on to the first notch in the reverse direction. The breaker can then be reset and the motor reversed. The limit switch should be of the totally enclosed self-resetting type.

Solenoids.

Solenoids for brake operation are preferably of the series type on direct-current circuits, but where rheostatic or dynamic braking is used they must be of the shunt type, in which case a discharge resistance should be fitted to take up the induced current on breaking circuit. For alternating circuits solenoids are preferably connected in all phases. The rating of a solenoid should be the same as the motor with which it is in circuit. The coils should be enclosed as a protection against damage, dirt, and damp.

The Lewis brake solenoid made by *Messrs. Ransomes & Rapier, Ltd.*, has two plungers, one sliding inside the other. The inner one is connected to the brake lever and is free to move independently of the outer plunger or armature. When the magnet is excited the two plungers are automatically and mechanically coupled and act as one in releasing the brake, but when the current is switched off they are disconnected and the inner plunger is free to follow the movement of the brake lever independently of the stroke of the magnet. As the brake surfaces wear the inner plunger is partially withdrawn from the outer, but owing to the automatic clutching arrangement, the full stroke of the magnet is always effective and releases the brake freely, obviating the rubbing and wear which take place with the ordinary brake if the shoes are not occasionally adjusted.

WIRING.

For crane work the current density may be in excess of ordinary practice for shop motors owing to the intermittent service, and the I.E.E. have drawn up a set of rules for this duty.

Cables, unless lead-covered and armoured, should be enclosed in metal conduits. Current is supplied to travelling cranes from bare conductors stretched along the track by means of slipper or trolley collectors. The bare conductors may be of copper wire, or, as is now common practice in steel works, steel tee or angle bars ground on the sliding face.

For jib cranes the conductors may be carried overhead or in a conduit. An alternative system is to run the cables in a closed conduit with junction boxes at intervals from which connection can be made by plug and flexible cable. A drum should be fitted on the crane to coil up the slack cable.

The drum may be hand operated if the crane is infrequently moved or if the length of travel is small, not exceeding 50 ft., and the cable light a spring can be used to automatically revolve the drum as the cable becomes slack and prevent loose coils lying on the ground. Where space will permit, it is better to have a weight-operated overhauling gear to exert a torque on the drum, and lengths of heavy cable up to 150 ft. long can be handled in this manner. Cable drums geared to the travelling motion are inadvisable owing to wheel slip on the rails, which may cause a considerable tension on the cable, with resulting damage.

Electro-Lifting Magnets.

Electro-lifting magnets are largely used in connection with cranes for handling all classes of iron and steel materials, and their application shows a considerable saving in time and cost compared with manual labour or even ordinary crane service with slings.

For lifting pig iron, small and heavy scrap, and large solid masses, a single circular magnet is adopted, and for lifting long and wide plates two or more of these magnets are used spaced along a beam which can be slung from the crane hook.

For rails and long bars or tubes a series of two or three rectangular or oval magnets on a beam are better, as greater lifting capacity is obtained with less dead weight.

The circular type of magnet consists of an outer casing or yoke of high permeability steel with a central boss which forms the inner pole of the magnet, the walls of the casing forming the outer pole. The annular space between the poles serves to contain a coil of high conductivity insulated copper wire or strip, secured in place and protected by a non-magnetic manganese steel bumping plate, the latter being held in position by the inner and outer pole shoes which are bolted to the casing and form the contact face of the magnet. In the 'Phœnix' magnet there are two annular recesses each with a coil; this construction increases the area of the central pole and adds to the lifting power of the magnet.

The outer casing is provided with lugs for attaching the sling chains, and a terminal box is fitted for making connection between the magnet coil and the supply cable.

Circular magnets are not suitable for stacking material in any systematic form, as the tendency with such magnets is to lift the material two or three deep only, where the centre pole gives contact, and a smaller quantity over the remaining surface of the magnet; consequently the quantity of material lifted is uncertain, and it is impossible to keep the stacks or banks in systematic heaps.

The Phœnix Patent Bi-Polar Magnet (fig. 12) has been specially designed for stacking systematically such material as rails, billets, ingots, bars, joists, etc. With this magnet the attractive force is distributed evenly across the pole faces, so that the magnet lifts and deposits the material in single layers without disturbing the underlying material. Further, it will lift single pieces out of a layer without disturbing the surrounding pieces. This systematic stacking is essential in works where large quantities of material are stored, and the use of the magnet must obviously effect great economies in time and labour.

The Phœnix bi-polar magnets can be used in several ways. The single magnet is used for lifting sections of comparatively short length—say up to 12 to 15 ft. To obtain greater lifting capacity with the same material than is given by a single magnet, two, three, or more magnets can be bolted together (see fig. 12, which shows three such magnets). When lifting material in long lengths, such as rails, a pair of single magnets are set at suitable centres and suspended from a lifting beam.

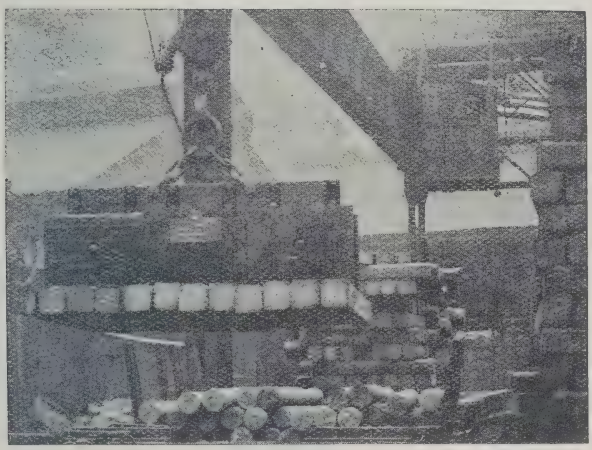

FIG. 12.

As regards the *lifting of hot material*, circular magnets are unsuitable, because they offer such large heating surfaces, and the windings are so close to the heat that there is bound to be overheating. The Phœnix bi-polar magnet offers the minimum surface to the heat, and when constructed for lifting hot material the pole pieces are extended about 8 ins. at the bottom to lift the coils farther away from the heat; the pole faces are then at a distance of 12 ins. from the coils.

The following typical cases are given to show the advantages accruing from the use of magnets:

1. 62-in. diameter circular Phœnix magnet, fitted on a 12-ton electric overhead crane, commanding a scrap storage ground. Weight of magnet about 65 cwts. Current consumption about 50 amperes at 220 volts.

2. A truck load of steel turnings unloaded in seven minutes, work which formerly took four men five hours.

3. Four large furnace boxes, each measuring 6 ft. by 2 ft. 7 ins. by 1 ft. 6 ins. deep, placed side by side on a rail lorry, filled in four lifts averaging 17½ cwts. each.

4. Four furnace boxes of the same size filled with 2½ tons of tube scrap in three lifts.

5. 52-in. diameter circular Phœnix magnet, handling steel turnings from stock heaps into railway trucks. Approximate weight of magnet 50 cwts. Approximate current consumption 40 amperes at 220 volts. The magnet made twelve lifts in seventeen minutes and handled in this time 95½ cwts.—an average of, say, 8 cwts. per lift. Steel turnings are difficult to handle, particularly if rusted together or with long turnings interlaced.

A 52-in. Phœnix magnet has also unloaded from trucks 600 tons of pig iron in 6¾ hours with the crane driver solely controlling the operations, no other labour being employed.

6. A pair of oval-shaped Phœnix magnets for handling combs of pigs. Without the magnets the time occupied to lift a bed of 22 combs was four hours; with one set of magnets the work is done in sixteen minutes.

With the magnets in use, only two or three ground men are employed, whereas hitherto 30 or 40 were required.

Steel may be handled by magnets up to a temperature of about 700° C.

The following table gives the approximate weights and lifting capacities with ingot and pig-iron for various sizes of circular lifting magnets:—

Diameter of Lifting Magnet.	Weight of Magnet.	Safe Load of Solid Steel Ingot.	Approximate Load of Pig Iron per Lift.	Current Consumption.
24 in.	5½ cwt.	5 tons	—	1·75 k.w.
36 ,,	16 ,,	7 ,,	9 cwt.	3·5 ,,
42 ,,	25 ,,	10 ,,	14 ,,	5 ,,
54 ,,	39 ,,	18 ,,	23 ,,	7·5 ,,
66 ,,	60 ,,	30 ,,	40 ,,	12 ,,

MOBILE FINGER MAGNET.

For lifting rails and bars of similar section, Messrs. Allen West & Co., Ltd., have developed a rectangular magnet (fig. 13) along the face of which are four rows of short steel pieces free

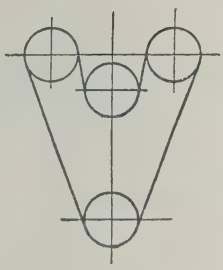
FIG. 13

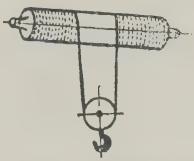
to move and adjust themselves to the contour of the bar to be lifted. Owing to these steel pieces forming a better path for the magnetic lines of force, the lifting capacity of the magnet is increased when dealing with irregular sections.

Vacuum Cup Lifting.

A German firm is using a system of vacuum cups, in place of slings, for handling non-magnetic plates with an overhead crane. A vacuum of 0·1 to 0·5 atmosphere is employed and is provided by a 5-h.p. rotary pump.

VARIOUS ARRANGEMENTS IN LIFTING APPLIANCES.





1.—One Bend.

Durability of Wire Ropes.

The two most important conditions appertaining to the manufacture and use of steel wire ropes that affect their durability are:

(a) Quality of material and size of wire.

(b) Diameter of pulleys and arrangement of ropes.

(a) Wire used for lifting ropes is of steel whose ultimate tensile strength varies from 80 to 130 tons per square inch. Ropes of material having a higher tensile strength are of smaller diameter for a given load and factor of safety, but since they are stiffer, larger drums are necessary to obtain the same durability.

The stress in a wire due to bending round a pulley is proportional to:

$$\frac{\text{(Modulus of elasticity)} \times \text{(Diameter of wire)}}{\text{(Diameter of pulley)}}$$

hence large wires are more quickly fatigued than small ones. On the other hand, small wires are more quickly worn through.

For a given ratio of pulley to rope diameter, given rope diameter and load, the life of the rope, if limited by abrasion and not by fatigue, increases as the square of the diameter of the wires of which it is made.

(b) For a given diameter of rope (d), diameter of wire (a) and load (P), the life of the rope depends on the square of the ratio of pulley to rope diameter (m) for large values of the latter.

The above statements have also been deduced from theoretical considerations by Prof. J. T. Nicolson, D.Sc., and may be represented by the formula given by him.

$$\text{Life of rope} = C\frac{m\,(m+1)\,d^2a^2}{P}$$

where the symbols m, d and a have the meanings given above, and C is a constant.

The practice of passing wire ropes on a crab as shown by fig. 14, entailing successively a 90° bend, a 180° reverse bend, and a 90° bend, is a bad one and deteriorates the strand wires;

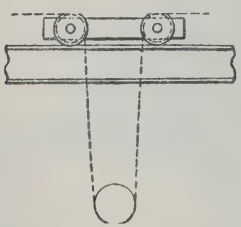

Fig. 14.

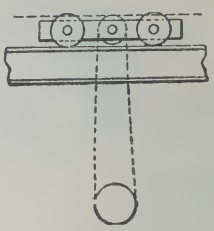

Fig. 15.

a better method is shown by fig. 15, the rope being taken over one upper pulley, down to the block, and up over the second pulley, the bend being always in the same direction, the reverse bend being thus abolished; this arrangement will increase the life of a rope as much as 50 per cent.

The effect of different arrangements of pulleys is shown by Nos. 1 to 7, page 825, and the accompanying tables, case No. 1 being taken as the standard.

† Points to remember in connection with wire ropes :

1. In general, use the lowest grade of steel.
2. In general, use the middle flexibility.
3. Use Lang's lay, if possible.
4. Ratio of pulley to rope diameter should not be less than 26 ; 30 is better.
5. If possible, employ a ratio of pulley to rope diameter of 40, and then keep to the lowest instead of the middle flexibility.
6. In the case of peculiar double turns, use pulleys as large as possible.
7. Avoid unnecessary reverse bends.
8. Keep the ropes well oiled.

* Including one reverse bend which is twice as effective in wearing out the rope.

† Mr. George Hughes, M.I.Mech.E., in Proc. Inst. Mech. Engrs., 1912.

LIFTS.

Notes on Lifts.

The usual height of a car from the floor to the top of the cross-head is 10 ft., and allowing the over-travel space or head room of 3 ft., this indicates that the minimum height to the underside of the floor of the engine or gear room from the top landing is 13 ft. The thickness of the floor depends upon the weight to be carried, but will not be less than 6 ins. When the engine is in the basement, 4 ft. is probably sufficient, but 6 ft. is desirable for the guide sheaves at the top of the shaft. Eight feet clear height should be regarded as the minimum for the engine room, whether it be situated in the basement or at the top of the shaft, and 9 ft. 6 ins. is desirable for the larger machines. Wherever possible a steel joist and lifting tackle should be installed in the engine-room to facilitate repairs when two or more lifts are provided.

The weight on the engine-room floor when the engine is located at the top of the shaft is, for a speed of 50 ft. per minute, approximately as follows, exclusive of the controller and cables :—

Car Capacity. *Passengers.*	Dead Load. *Tons.*
6	2·6
9	3·4
12	4·6
15	5·5
18	6·5

An allowance of 2 sq. ft. per passenger and 4 sq. ft. for the attendant (to enable him to handle the controller, car gate, and landing doors rapidly) is the usual basis for figuring car capacity ; for instance, a car having a floor area of 6 ft. by 5 ft. = 30 sq. ft. would have a passenger capacity of 30 less 4 = 26, which divided by 2 gives 13 passengers.

Similarly, the weight of the average individual has been ascertained to be 140 to 150 lbs. and, therefore, the assumed load is figured at 75 lbs. per sq. ft. of floor area.

Convenient car sizes are as follows :—

Depth.	Width.	Area.	Passengers.	Attendant.	Total.	Live Load.
ft. in.	ft.	sq. ft.				lbs.
6 0	7	42	19	1	20	3,150
5 0	6	30	13	1	14	2,250
4 4	6	26	11	1	12	1,950
4 0	5	20	8	1	9	1,500
3 0	4	12	4	1	5	900

In modern office buildings up to ten floors a very useful size for the car is 5 ft. wide by 4 ft. 4 ins. deep (*i.e.* 21·5 ft. super., carrying eight to nine passengers). Large departmental stores of the Oxford Street, Regent Street, and Kensington type generally require a larger car, and in this case the size is frequently 8 ft. wide by 6 ft. deep, giving a floor area of 48 sq. ft., and designed for a maximum load of 3,600 lbs. With these exceptions a 6 ft. by 6 ft. car is generally regarded as the largest standard car, rated for sixteen passengers and a gross load of 2,700 lbs.

Details of Tee Guide Rails.

Lbs. per foot run.	Width of Base (ins.).	Height of Web (ins.).	Width of Web (ins.).	Remarks.
$6\frac{1}{2}$	$2\frac{3}{4}$	$1\frac{5}{16}$	$\frac{21}{32}$	Counterweight Car
14	$4\frac{1}{2}$	$3\frac{7}{16}$	$\frac{21}{32}$	
21	$5\frac{1}{16}$	$3\frac{17}{32}$	$\frac{5}{8}$	
39·4	6	$5\frac{3}{16}$	1	

Guide rails, which are either cold-rolled or planed steel, are usually supplied in 14 ft. to 16 ft. lengths. Alignment is secured by groove-and-tongue joints and a splice plate bolted at the

back. Splice plates for car guides are frequently specified to be not less than 12 ins. long, four ⅝-in. bolts being required for each end of the guide. For counterweight guides, which are not called upon to stand heavy strains from the safety gear, 9-in. plates and ½-in. bolts are accepted. In cases where the supports on wall fixings are at a greater distance apart than 12 ft., angle iron or channel iron stiffeners are used, which run about 9 to 10 lb. per foot.

Guide grips should have a minimum clearance of ⅛ in. to avoid the risk of their being brought into action accidentally.

Usually the empty car is overbalanced to the extent of 40 per cent. of the maximum passenger capacity of the car, which has been shown to be the average load if the equipment is well designed. Careful balancing not only has a marked effect on the consumption of electrical energy, but also on the speed of an empty descending car and proper upward stopping distance.

As a very rough guide, the following figures are given for speeds :—

Travel of Car.	Load Speed.
30 to 40 ft. . . .	150 to 200 ft. per min.
45 to 70 ft. . . .	180 to 250 ft. per min.
75 to 100 ft. . . .	222 to 300 ft. per min.
100 ft. and over . .	300 to 400 ft. per min.

Due allowance must, of course, be made for car size, distance of average non-stop run, etc. In New York City, 500 ft. per min. is the legal limit of speed for local elevators and 700 ft. per min. for expresses, *i.e.* when there is a clear non-stop run of 80 ft.

Over-travel spaces at both the top and the bottom of the shaft are essential, as the brake is subject to wear and cannot be relied upon for accurate floor levelling, especially with high-speed traction machines.

The depth of the pit or sump—*i.e.* the over-travel at the bottom of the shaft—should be 3 ft. 6 ins., measured from the lowest landing. For higher speeds the space must be increased to 4 ft. 6 ins., and for traction-drive express lifts 7 ft. 6 ins. may be required. As an additional precaution against jar or shock, should the brake slip, spring or oil buffers are used under the car and also under the counterweight. The cost of a spring-loaded set, of a simple character, is small, and the installation is strongly recommended.

A clear space of 3 ft. is usually the minimum required between the top of the crosshead of the car and the underside of the shaft ceiling when the car is at its top landing. For speeds above 350 ft. per minute, 5 ft. is regarded as the minimum space.

All footings for columns and for foundations adjoining lift shafts should be carried below the pit in order to ensure that all sides of the pit are true and plumb with the finished sides of the shaft. Similarly, off-sets on the inner sides of the shaft walls should be avoided wherever possible, since the working forces of both the car and counter-balance weight guide rails must be truly vertical, and any inaccuracy in the builders' work will involve considerable additional expenditure for erection of the lifts.

A clear space of not less than 3 ft. should be provided between the bottom of the shaft and the lowest point of the underside of the car floor when the car is standing at its lowest landing, and between the top of the cross-head of the car and the underside of the ceiling of the shaft when the car is at the top landing. For express lifts these over-travel spaces must be increased up to a maximum of 7 ft. for the highest speeds, and even for slow-speed alternating-current lifts 4 ft. is desirable.

Collapsible gates are not desirable for brick shafts on account of the added fire risk, due to flue effect, and also because of draughts. The type of door should be that best adapted to the particular type of car to be installed, and the width of the opening should be such that ingress and egress will be as free as possible—usually 66 per cent. of the width of the car, in order to provide standing space for the attendant. Adequate allowance should be made for floor projections into the shaft, which vary with the type of door adopted, viz. combination slide and swing single slide; double doors sliding in the same direction; double doors sliding in opposite directions; double swing doors, etc. Wired glass panels should be provided in all landing doors to avoid accidents when opened quickly. The standard height of landing doors is 7 ft., and the minimum width should be 2 ft. 6 ins.

(*'The Builder,' Jan. 6, April 7, 21, 1922—Abstracts.*)

ELECTRIC LIFTS.

Typical Specification for Electric Lift.

The following are the main particulars of the lift :—

Extreme travel . . 38 ft. 9 ins. Speed . . . . 120 ft. per min.
Maximum load to be carried, 10 cwt. Inside dimensions of cage, 3 ft. 6 ins. × 3 ft. × 7 ft. high.

Position for Motor, etc.—The motor, etc., to be placed in the basement in the position shown in the plan.

If fixed overhead, the driving sheave or drum should be designed, if possible, to span correctly from the centre of cage to centre of weight, so as to save the use of diverting sheaves.

The overhead sheaves are to be supported on suitable rolled steel joists, to be supplied and put in position by the contractor.

Cage.—The cage walls are to be made of well-seasoned pine, with a substantial iron or steel framework, and adjustable guides at the top and bottom to work on the runners. No seat will be required. A Bostwick or other approved sliding gate to be provided at the cage entrance.

The construction of the cage may be either (*a*) framed with grooved and tongued panels, the woodwork forming the panels being put in diagonally, and the whole bolted to the iron framework of the cage ; or (*b*) of grooved and tongued planks on the flat bolted to the iron framework of the cage with an additional strengthening iron ; or (*c*) of an approved type. If method (*a*) is adopted, the framing must not be of less than 1½ in. stuff, and the panels not less than ⅞ in. ; if (*b*) the planks must be uniformly 1 in. thick. The floor of the cage must be of maple, 2 ins. thick. All the above dimensions are finished sizes.

An opening to be provided in the top to allow for the lighting of the cage by daylight. This opening is to be covered over and under with iron wire trellis of 1 in. mesh, of not less than No. 13 S.W.G. The wirework to be galvanised after it is made up.

The interior of the cage, with the exception of the floor, to be varnished with three coats of good oak varnish.

The cage to be fitted with an electric light fitting of the bulkhead or other approved type, with genuine enamel reflector. A bayonet collar lamp-holder, lamp, cut-out and tumbler switch for this fitting, and a length of flexible cable for making connection to a ceiling rose fixed about half-way down the lift-well, to be provided and fixed by the contractor.

Electric Bell.—Suitable bell pushes are to be provided and fixed on each landing, and connected to an electric bell, to be provided and fixed in and about midway up the lift-well, and to an indicator for each floor, to be provided and fixed in the lift cage. A battery for working the bell is to be provided.

The whole of the bell work, including the necessary wiring, is to be done in the most approved manner.

Gates for Cage and Openings in Lift Well.—Collapsible gates, with spring-catch lock of the Bostwick, B. and S., or other approved pattern, are to be provided and fixed to the lift-well openings on each floor, to the lift cage and motor enclosure. Six gates in all will be required. The locks and gates (except in the case where push buttons are required to be fitted) to be so constructed that they cannot be opened except by use of the authorised key.

The gates, which are to be carefully finished black, are required to open the width of the cage opening, and to reach to the top of the cage opening.

Lift-Well Enclosure and Wirework Guards.—A wirework guard is to be fixed to the gate uprights, and continued round the lift-well above and below the hand-rail from the basement to the second floor at a height of 7 ft. from the stair treads. Suitable supports for the attachment of the wire guard are to be provided, and care is to be taken to prevent the guard or its supports from interfering with the free use of the stairs hand-rail. The guard is to be over and under iron trellis of 1 in. mesh, not less than No. 13 S.W.G., and is to be finished black, and stiffened where necessary by angle iron or tubing.

A wirework screen with suitable channel iron supporting frame, at least 7 ft. high, with Bostwick gate, to be provided in the basement for the protection of the motor and gear.

*Carrying Capacity and Speed.**—The cage to carry a maximum load of 10 cwt., and to travel at a speed of 120 ft. per minute when fully loaded. The maximum variation of speed ascending or descending at any other load must not exceed 10 per cent.

* In the case of passenger lift with car switch operation, the speed is now from 200 to 300 feet per minute.

Safety Devices.—The most improved system of safety devices is required. A full description of all safety devices to be employed is to accompany tender. They must include the following :—(*a*) The locking of the cage on the guides or guide backings if one or more of the suspending ropes break or slacken ; (*b*) automatic stopping of the motor when the cage is brought to rest from any cause, unless the V wheel drive is used ; (*c*) automatic stopping of the cage before it reaches the top or bottom of the lift well.

Painting.—The whole of the materials fixed and supplied by the contractor, with the exception of the electric light and bell fittings, cables and resistances, bright metal work, folding gates, and the inside of the cage, which is to be varnished, is to be painted with three coats of oil paint, the finishing coat to be of a colour to be selected. The wood work, including all portions of the cage which are not visible, is to be knotted and primed before being painted.

Lubrication and Contact Cleaning.—The whole of the plant is required to work automatically and to require no attention beyond occasional lubrication, and occasional cleaning of the contacts.

Factor of Safety.—The factor of safety for the suspending ropes is to be not less than ten, and for all other parts a factor of safety of at least five is to be provided.

Precautions against Fire.—The contractor is required to make such arrangements as will prevent an outbreak of fire should the armature or any other part of the apparatus fuse or become excessively hot.

Quality of Material.—The material and workmanship to be of the best possible description throughout.

Tests.—Immediately the lift has been erected, the contractor will be required to make the following tests to the satisfaction of the inspecting officer :—

1. The cage to be loaded until the weight on the ropes is twice the combined weight of the cage and specified maximum load. The gear and suspending ropes must bear this weight for 30 minutes without showing any sign of weakness, temporary set, or permanent elongation of the rope strands.

2. Tests to determine if the specified speed is complied with.

3. Tests to determine if the various safety devices comply with the conditions of the contract. These are to include : (*a*) Starting the cage up and down and letting it run to the end of its journey without attention ; (*b*) slackening one or more as required of the suspending ropes.

4. Tests to determine the suitability of the switching gear.

The contractor is required to provide a man to start the lift and to attend to it for one week from the time when it is accepted as running satisfactorily.

Leading makers such as *Smith, Major & Stevens, Ltd.*, use the following speeds on their lift motors, for continuous current :—

Up to 3 h.p. . . .	1,000 revs.	Up to 7½–10 h.p. . .	650–750 revs.
„ 5 „ . . .	930 „	„ 15 „ . .	500–700 „

For single phase, 50 periods, 6 pole machines usually.

For 2 and 3 phase, 50 periods, 6 pole up to 10 h.p., and 8 pole above.

Ropes for Lifts.

See British Standard Specification for Round Strand Steel Wire Ropes for Lifts and Hoists No. 329, 1928.

ELECTRIC WINDING.

The Ward Leonard System.

(English Electric Co., Ltd.)

This system (fig. 16) is based on the fact that the speed of a separately excited D.C. motor is directly proportional to the voltage applied to the armature. If, therefore, the D.C. motor, 1, is used to drive the drum D, it can be made to run at any desired speed and in either direction of rotation, by varying the voltage and direction of the current impressed on the armature. This D.C. power is obtained from a separate generator, 2, known as the variable voltage generator, and driven at constant speed by a motor, 3, connected to the supply mains. The variable voltage generator and its driving motor are coupled together and mounted on a common bedplate, which also carries, on the same shaft as the other two machines, a small D.C. generator. This generator supplies the excitation current to the variable voltage generator and the winding motor, the triple combination being known as the converter set.

A regulator, 5, is used to vary the field of the V.V. generator and, consequently, its voltage between 0 and a ± maximum, and in this way the speed of the winding motor to which this voltage is applied can also be varied between zero and ± maximum.

The principal feature of the control is that the speed and direction of rotation of the winding motor are determined solely by the regulator or, in other words, by the position of the driver's control lever. For all practical purposes this holds true whatever the load in the cage may be, and whether the load is being raised or lowered. When in a running position—by moving the control lever towards the 'off' position—a strong electrical braking effect is obtained, as the motor then acts as a generator and returns energy through the converter set to the line. The same electrical braking effect can be obtained when lowering loads, and the low speeds required for inspection tests can be readily obtained by a slight movement of the lever from the 'off' position.

It should be noted that the controller only deals with the field of the V.V. generator (about 2 to 3 per cent. of the output), consequently, it is very small as compared with an A.C. controller, and can be readily operated even on the largest winders without the use of auxiliary gear.

As any given position of the control lever corresponds to one speed only, and one direction of rotation, it is possible to provide simple safety appliances of absolute reliability.

In Fig. 17 is shown diagrammatically the system used by the *English Electric Co.* for the automatic control of the acceleration and retardation.

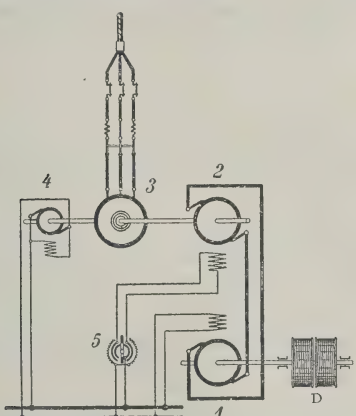

FIG. 16.

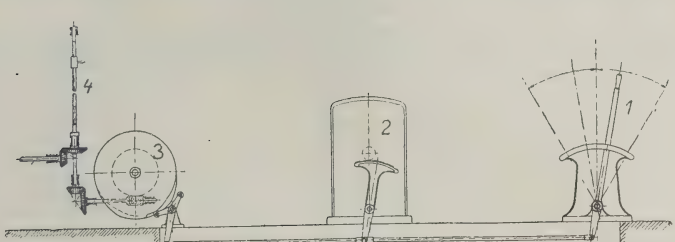

FIG. 17.—Diagram of Depth Indicator with Safety Device as used by the English Electric Co., Ltd.
(1) Operating Lever. (2) Controller. (3) Control Cam. (4) Depth Indicator.

The spindle of the depth indicator drives two cam wheels, one for each cage, through gearing proportioned so that the wheels make nearly one complete revolution. Each wheel has two cams, one for acceleration and one for deceleration. When starting, the control lever can only be moved from its mid position at a rate determined by the shape of the cams, which shape is designed to give the predetermined rate of acceleration. This rate cannot be exceeded. When retardation should begin, if the driver has not already started to bring back his lever, the deceleration cam gradually forces the lever back to the 'off' position. Acceleration, retardation, and speed of wind are thus within the driver's control, provided he does not attempt to exceed the limits for which the cams are designed.

In the event of an overspeed, electric braking automatically takes place. The winding motor will act as a generator and supply power to the V.V. generator, which will then act as a motor driving the set above synchronous speed, causing the induction motor to act as an asynchronous generator and pay back power to the line. Should the speed of the set exceed a predetermined maximum, a centrifugal switch driven from the shaft of the set will open the circuit of the brake magnet and apply the emergency brake.

AERIAL ROPEWAYS.

Aerial Ropeways may be divided into two fundamental types:—The SINGLE ROPE or MONOCABLE, and the DOUBLE ROPE or BI-CABLE. In the first, a single endless rope is used both to support and move the loads. In the second, there are one or more supporting ropes and an endless hauling rope. Adapted to these types are the 'Fixed or Non-detachable Clip System,' on the Single Rope Type, and the 'Jig-back' or 'To-and-fro System,' which is applicable to either type.

There is considerable divergence of opinion upon the merits and demerits of the two systems, which is due largely to the fact that a number of plants have been installed without giving due consideration to which type is most applicable to the nature of ground to be traversed, and the duty to be performed.

THE SINGLE ROPE OR MONO-CABLE SYSTEM.

Ropes.

By experience, it has been found the most suitable form of rope on an average length line is a 6·7 Lang's lay, with a specially hard hemp core. On short lines when the rope is subject to a great number of bends per hour around the terminal sheaves, compound lays are sometimes used. Wire cored ropes are also occasionally employed, owing to the fact that they tend to stretch less than those with hemp cores, but they have been found by experience not to have such a long life.

On a well-constructed line, depreciation on rope is covered by ·125 pence to ·3 pence per ton mile carried, on the basis of a line not less than 1,000 yards long, and a capacity of over 25 tons per hour; as the length and capacity increases, the depreciation per ton mile carried decreases. The fact that on a single rope system the entire length of the rope is constantly passing under observation at the terminals renders it very safe against failure, and it can be worked until a comparatively low factor of safety is reached. The diameter and breaking strain of ropes can be obtained from the formula given on page 839, under 'Diameter of Hauling Ropes.' No rule can be given, however, for finding initial tension, as this is dependent upon driving power required and spans to be negotiated, etc., apart from capacity of line and so forth.

Loads.

When possible, individual loads should be kept to about 1 per cent. of the hourly capacity of a line, for the purpose of distributing the weight on spans. Heavy individual loads tend to increase prime costs.

Carriers and Clips.

Among the best known are Roe's Patent Toggle and Saddle Clips.

The former, fig. 18, is capable of sustaining a load at an angle of over 45°, and in theory is the most efficient of all clips actuated by the load, as the whole of the tare weight also is used

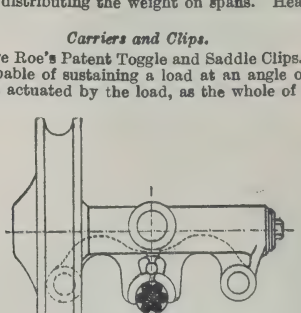

FIG. 18.

for gripping. In practice, however, the saddle clip, fig. 19, is found preferable and is usually adopted. The gripping in this type is performed by two cast chilled saddles, the sides of which are inclined, one side having a feather projection which engages into the lay of the rope, this projection being so formed that it disengages itself without damaging the strands when the carrier enters a station. The ruling grade on which this type of clip can be safely worked is 1 in 2¼. The tare weight of clip, carrier, and bucket is usually about one-third of the net load.

Fig. 20 shows the 'Roe Balance Beam.' The arrangement is used for distributing the pressure equally on a series of sheaves; these are arranged in groups of 2, 4, and 8. The introduction of a number of balanced sheaves in series greatly facilitates the working of long spans, and reduces wear and tear of rope where heavy pressure on any trestle has to be sustained.

A fair speed for the rope is 400 ft. per minute, though under certain conditions it can be run up to 550 ft. per minute, when no automatic return or dumping is required. The factor that rules the speed is the velocity at which the loads can be brought up to for engaging

with the rope, bearing in mind that the load and rope velocity should synchronise at the point of attachment.

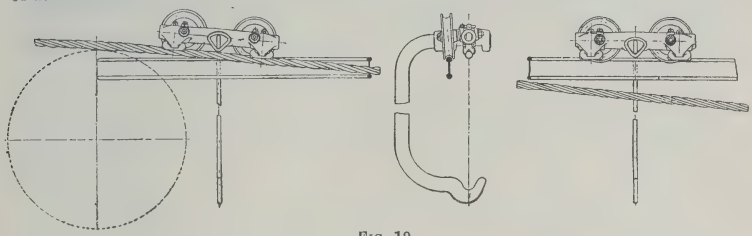

FIG. 19.

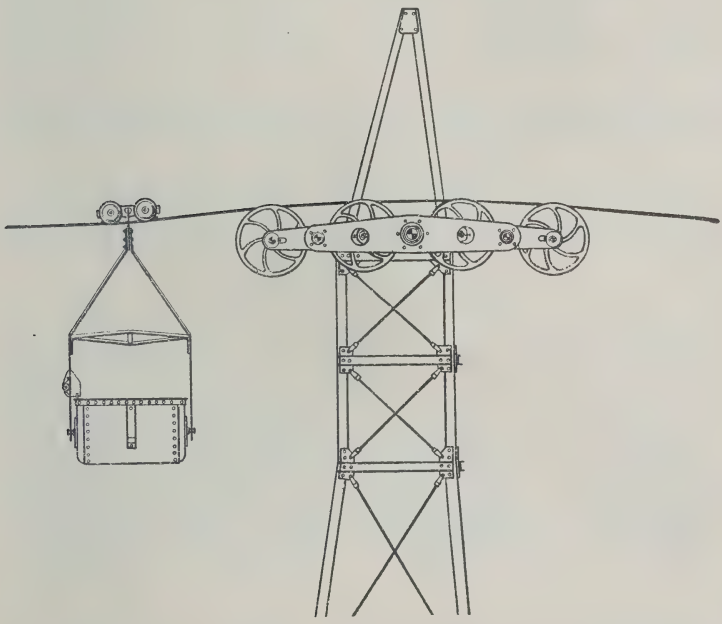

FIG. 20.

Power.

Any available power can be used as long as it is steady. Trouble, however, may be caused by using intermittent power, as this gives rise to oscillation of the rope in long spans. On automatic lines, the surplus power is preferably absorbed by means of a fan or turbine. When possible, the power should be placed at the upper end of a line, and the tension at the lower terminal. In long lines that have to be sectionalised, the driving or brake station, as the case may be, is sometimes placed between two sections, and the tension arrangements at the ends.

Tension.

To ensure a constant and even tension, it is essential that the counterweights should be always free and floating, and owing to the amount of stretch in hemp cored ropes, taking-up gear must also be allowed for. Fig. 21 shows an arrangement which combines a multiplying and taking-up device. The two sheaves at A are attached to the tension trolley, the winch and differential drum being mounted on an independent frame placed over the tension

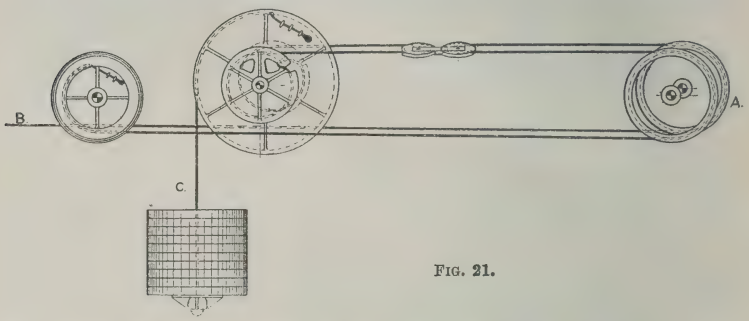

FIG. 21.

pit; one end of the rope B is anchored, the other being made fast to the tension winch drum. By this arrangement the resultant pull at A is four times the dead weight applied at C, and the weights can always be kept in suspension without the necessity of a deep pit, by taking in the slack with the winch.

Spans.

The distance between standards is dependent on the configuration of the ground, but over undulating country the average distance is approximately 330 ft. for lines of up to an hourly capacity of 60 tons. On a ropeway over the Andes, having a total length of 46 miles, several spans are being worked of 2,800 ft., though the longest recorded span on the single rope system is 3,600 ft.

DOUBLE ROPE OR BI-CABLE SYSTEM.*

Carrying Ropes.

Carrying ropes may be divided into two main classes, 'spiral,' fig. 22, and 'locked coil,' fig. 23. The main advantage of the spiral type is its cheapness, and in lines transporting a small tonnage

FIG. 22.

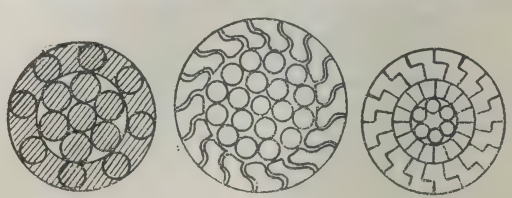

FIG. 23.

per hour it will generally answer its purpose. Ropes of this type should consist of 19 wires in ropes up to 1 in. diameter and of 37 wires in ropes up to 1½ in. diameter. With this latter the individual wires have a diameter of about ·205 in., which is about the limit to ensure perfect homogeneity of the material. Above 1½ in. diameter, locked coil ropes should invariably be used.

Locked coil ropes, fig. 23, are of two types, the special locked, *a*, and the full locked, *b* and *c*. The former consists of a spiral core surrounded by a layer of round wires kept apart by wires

* Abstract from 'The Engineer,' July 23, 1915

drawn to a special section. This rope is sold at a medium price between plain spiral rope and full locked coil. The surface of the special locked rope is not perfectly smooth, small interstices occurring between the wires. The full locked coil, on the other hand, presents a perfectly cylindrical surface to the passage of the cars. The second type of full locked construction—shown at *c*—is particularly useful for very heavy carriers, as, owing to the rope having an inner layer of tapered section wires, the crushing and distorting effect of the load when passing over the saddles on which the rope is supported is minimised. In addition to the great advantage of offering a smooth surface to the wheels of the cars (with the result that the wires may be of a lower breaking stress than with spiral ropes), the locked coil ropes possess the great advantage that, should by any chance one of the individual wires break, it is held in place by the neighbouring wires, and does not spring from the texture of the rope, as is the case with the spiral construction. This springing of the wires is often the cause of accidents, as the cars run against the outstanding wire, and are thrown off the line.

Fixture of Ropes.

The ropes are anchored at one end of their length, and some form of tensioning device applied at the other end. This generally takes the form of a hanging weight, which may generally be from one-quarter to one-fifth of the total breaking strength of the rope. A factor of safety of 4·5 is a good medium. It has been proved that for spiral ropes a breaking stress of 95 tons per square inch, and for the locked coil ropes 65 tons per square inch, give the best results. When calculating the tension weight required, the fact must be taken into account, that should the weight be situated on a lower level than the anchorage, the weight of the rope itself acts as a tensioning factor.

For fixing the ends of the rope a satisfactory arrangement is to employ the ring wedge coupling. In this anchorage—shown in section in fig. 24—the single wires are kept apart by small nail-like

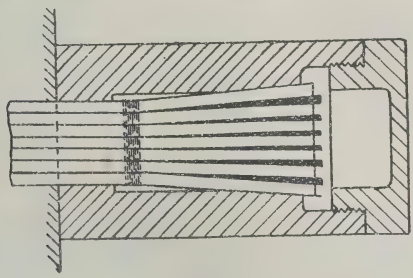

FIG. 24.

wedges, and the layers by means of ring wedges made in halves. These wedges are driven in and then a cap is screwed home, firmly locking them in place and entirely preventing any chance of the wires pulling out.

The same form of coupling, only made tapered at both ends, fig. 25, may be used for joining the various lengths of rope along the line.

FIG. 25.

The distance apart of the tensioning weights varies according to the carrying capacity of the line, weight of carriers, number of long spans occurring, etc. A good rule is not to exceed a length of 1½ mile between anchorage and tensioning device, although on level lines, with a small capacity, distances up to 2 miles may be taken.

Another method of tensioning is by means of buffer springs at either end of the rope, but this system is only applicable to short lines with light loads.

Diameter of Carrying Ropes.

It has been proved by experience that most trouble is caused by breaking due to bending near the saddles, and for this reason in order to obtain the diameter of the carrying rope

required, many firms employ formulæ based on stresses due to bending. A formula often used is :—

$$\text{Weight per metre of ropes} = \frac{0{\cdot}85}{100}\left\{(\text{weight of carrier}) + \Big((\text{distance between carriers in metres}) \times (\text{weight of traction rope per metre}).\Big)\right\}$$

This is for spiral construction ropes. With locked coil ropes the factor 0·85 becomes 1·05. This works well for small lines up to about 50 tons capacity hourly. For each additional 5 tons, 0·05 should be added to the factor 0·85. The following table shows the various diameters of a special locked rope for various loads and traction ropes :—

(Two-Wheeled Carriages.)

Dia. of Hauling Rope.	Weight of Loads in Cwts.

Design of Ropeway.

To lay out the profile for a ropeway, when the line is laid out on paper, the curve of the rope may be obtained and set out from the formula—

$$\text{Dip} = L^2W/8T,$$

where,

L = span ; W = weight per unit length ; 8 = constant ; T = tension,

and then the supporting trestles placed accordingly. It sometimes happens, however, in practice that when the rope is fully tensioned it 'floats' or rises up from the supporting tower, owing perhaps to a minute error in the drawn profile. To avoid this, some Continental makers employ a so-called factor of safety for the dip—that is, the denominator 8T is multiplied by a constant —the formula giving, as a result, a dip smaller than the actual. It will be obvious that if the curve with the dip so obtained is set out and the trestles drawn up to it, they will be slightly higher than need actually be the case, thus avoiding any possibility of 'floating' when the line is erected. This factor of safety may be 1·5 for spiral ropes and 1·1 for locked coil ropes.

There has been of late years an increasing tendency to employ saddles (upon which the rope is supported at the trestles) which are pivoted at the centre, and can consequently adapt themselves to the varying gradients of the rope, and there is little doubt that this type when properly designed, and well greased to allow of play in the rope, gives full satisfaction. In designing the shoes a good medium value for the pressure of the rope is 250 lbs. pressure per square inch of projected area of the rope. This is for locked coil ropes ; for spiral ropes a little less should be taken.

It sometimes happens that at a trestle, on either side of which are long free spans, there is a heavy downward reaction of the hauling rope, which, when the carrier passes over the saddle, produces a heavier pressure on the rope than that for which it was calculated. In this case the rope is protected by means of a steel plate cap over which the carrier runs, thereby removing the pressure from the rope. There is a difference of opinion as to when these caps should be employed, but it may safely be said that their use is to be recommended where the hauling rope reaction exceeds 450 lbs.

Hauling Ropes.

The *traction* or *hauling rope*, by means of which the carriers are propelled, is invariably a stranded rope with a hemp core, the flexibility depending on the size of the individual wires in the strands and the breaking stress of the material. This rope is endless and in constant motion. In the general case it passes round a driving sheave at one end of the line and round a surging or tension sheave at the other end. In some cases this plan may be varied, as, for instance, when the carriers are required to pass automatically round a large sheave at one end station. In this case no manual attention is required at this station and the driving and tensioning sheaves are combined in the station at the opposite end of the line. Whenever possible

the driving should take place at the upper and the tensioning at the lower end of the line. In this way the accumulative tension in the rope due to its own weight is utilised as a tensioning agent, whereas, were the tensioning to take place at the upper end, an additional amount of weight would be required to counterbalance the weight of the rope. The amount of the tensioning weight should be such as to give sufficient grip round the driving sheave to ensure perfect driving when the full load is on the line.

Diameter of Hauling Ropes.

The diameter of the hauling rope depends upon the highest tension occurring in it.

$$\text{Tension of rope in lbs.} = \left\{\text{Initial tension} + \left(\frac{W}{S} \times H\right) + (w \times H)\right\} + \left\{(W \times \mu_1 \times N) + (L \times \mu_2 \times w) + (R \times 2)\right\},$$

where,

W = weight of full carrier; S = spacing of carriers in feet; H = difference in level between stations in feet; w = weight per foot of traction rope; μ_1 = coefficient of friction of cars; μ_2 = coefficient of friction of traction rope; L = length of line in feet; N = number of carriers on one side of line; R = number of supporting rollers on one side of line.

This tension if multiplied by the factor of safety—6 to 8—and divided by the breaking stress, gives the area of the rope necessary. This is for the general case with the drive at the upper terminal and the loads ascending. When the loads are descending, the plus sign in the centre of the formula becomes minus. To obtain the tension when the ropeway is just put into work the second half of the formula should be doubled.

The usual breaking stresses of traction ropes are from 80 to 115 tons per square inch. The surge of the hauling rope tension sheave depends upon the distance apart of the carriers, whether long spans occur in the line, etc. As an average, 6 ft. play may be allowed for to commence with, and then an additional 12 ft. for each mile of length. In some cases in long lines it is necessary to split up the line into sections to avoid excessive tensions occurring.

Driving Power.

$$\text{Power in ft. lbs.} = \left\{\left(W_1 \times W_2 \times \mu_1 \times \frac{N}{2} \times V\right) + (w \times 2L \times \mu_2 \times V) + (2R \times V) + (F)\right\} + \text{or} - \text{theoretical power},$$

where,

W_1 = weight of full carrier; W_2 = weight of empty carrier; μ_1 = coefficient of friction for cars; N = total number of cars on line; V = velocity in feet per minute of cars; w = weight per foot of traction rope; L = length of line in feet; μ_2 = coefficient of friction for traction rope; R = number of supporting pulleys; F = power required for station friction.

The first four factors give the power necessary to overcome friction, and the theoretical power required or developed depends upon whether the loads are ascending or descending. The factor for station friction varies greatly for different lines, and is solely a matter of experience, although 0·02 of the total weight of the moving parts on the stations multiplied by the speed may be taken as a good mean.

Carriers.

There are two kinds of carriers in general use, those employing screw grips and those with lever grips. These may again be divided into sections, the overtype and the undertype grips. In the former, the hauling rope is attached to the carrier or running head at a point above, and in the latter at a point below the carrying rope.

The main advantage of the overtype grip is that the length of the stations is shorter than with the undertype grip, as the hauling rope may be led in and out of the jaws without interfering with the shunt rails. In the case of lever grips the overtype is generally the cheaper, and on lines containing no steep gradients can often be employed with advantage. Further, it may be more easily adapted for taking curves in both directions than the undertype. The overtype grip has, however, several great disadvantages. Chief amongst these is the fact that when ascending steep gradients the traction rope reaction falls outside the wheel base, tending to tip the whole running head, a tendency which may not be counterbalanced by the weight of the carrier, with the consequence that the whole apparatus leaves the line. Again, owing to the fact that the centre line of the hauling rope must fall outside the centre line of the carrying rope to avoid any entangling, there is a decided tendency for the carrier to tip sideways as soon as a heavy hauling rope reaction occurs, a tendency which is very detrimental to the perfect working of the line when it is required to discharge the contents of the carrier automatically whilst the carriage is on the open track. These defects may be remedied by having the hauling rope directly below the carrying rope, *i.e.*, using an undertype grip. Practically the only defect

of this type is that the stations are generally longer than with the overtype grip, thus involving extra structural work. Even this may be overcome by employing an undertype grip in which the jaws open downwards instead of upwards, as is usual.

The speed at which the carriers should be run depends upon whether it is necessary for them to be hauled automatically round curve or return sheaves by the traction rope. The following figures represent good practice :—

Straight lines	400–450 ft. p.m.
Curves up to about 45° change of direction	Undertype up to 400 ft. p.m. Overtype „ 300 ft. p.m.
With automatic haul-round—	
Sheave, 20 ft. dia.	Undertype, 350 ft. p.m. Overtype, 300 ft. p.m.
Sheave, 16 ft. dia.	Undertype, 300 ft. p.m. Overtype, 250 ft. p.m.
Sheave, 12 ft. dia.	Undertype, 200 ft. p.m. Overtype, 150 ft. p.m.

The running wheels should be of high quality cast steel, the diameter depending on the load and type of rope, larger diameter wheels being employed with spiral ropes than with locked coil. The runner pins should be self-oiling. The following table gives some diameters of wheels for varying loads, carriers with two wheels being employed :—

Weight of load and carrier, cwts.	Diameter of wheel, ins.
14	8
30	10
40	12

Screw Grips.

There are two distinct main classes of screw grip, in the first of which the grip is operated by a lever and strikers in the stations. In the second the grip is operated by the weight of the carrier and load. The best example of the former is shown in fig. 26. There are two jaws—(*a*) the movable and (*b*) the fixed. The movable jaw is actuated by a shaft carrying two screws, one a rapid thread and the other a fine thread. This shaft is turned by the lever C. The action of the grip is as follows :—On the lever C being turned over, the rapid thread operates and the movable jaw quickly approaches the fixed jaw until the rope is just gripped. The fine thread now comes into action and applies the necessary force to grip the rope firmly. To unlock the

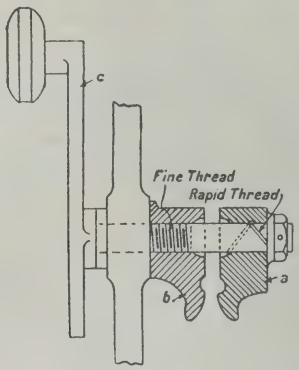

FIG. 26.

grip the reverse action takes place. The lever C is actuated at the stations by strikers constructed of angle irons.

In the other form of screw grip, in which the pressure is obtained from the weight of the carrier and load, the action is the same, the necessary turning moment being applied to the screw by hanging the carrier at the end of the lever arm. The grip is opened to allow of the rope entering or leaving, by means of rails, generally formed of angle irons, which depress small pulleys fixed at the end of the lever arm opposite to that on which the carrier is hung, thus raising the latter and thereby opening the jaws. It has been found in practice that the position of this lever arm should not be less than 35° to 40° to the vertical, to allow of easy depression of the rollers.

Lever Grips.

One of the best known Continental types is that shown in fig. 27. In this grip the pressure is applied by the weight of the carrier and load acting through a simple system of levers to give a multiplied pressure on the jaws. The grip is released by lifting the load, which is accomplished by means of small rollers running on to rails in the stations. Another type of grip—the

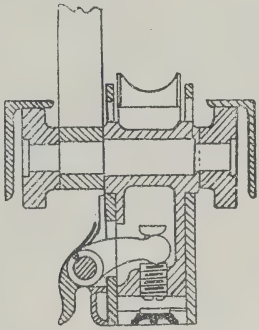

FIG. 27.

inclined plane type—is illustrated in fig. 28. The carrier and load are attached to a hanger having at its upper end a curved slot. This slot engages with a circular pin attached to the movable jaw. The downward pull of the hanger draws in this pin and with it the movable jaw, thus closing it upon the rope. When the pin is in the upper part of the slot the grip is absolutely locked, as no amount of upward pull of the rope can force the jaws apart. The grip is released

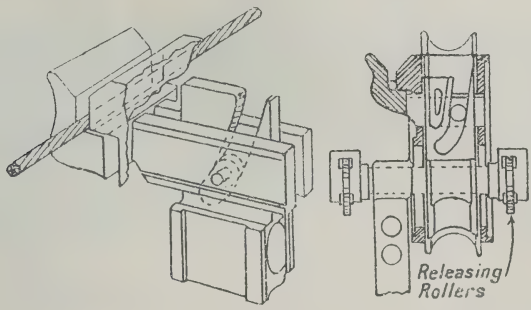

FIG. 28.

in the stations in the same manner as the type shown in fig. 27. In practice this form of grip has been found extremely simple and efficient.

In the matter of taking curves automatically in both directions, the advantage lies with the lever type of grip. In cost the latter generally has a great advantage. A ropeway with lever grips, carrying two-ton loads on an incline of 86 per cent., is being used for carrying timber in South-West Africa.

*Costs.**

The following tables of prime and working costs for ropeways represent the standard amounts for plants possessing no peculiar complications.

* The figures given are those current some time prior to the war.

Prime Cost of Plant with Structures in Steel.

Capacity in Tons per Hour.	Length of Line in Miles.			
	½	1	2	5
	£	£	£	£
5	1,900	2,000	3,300	6,900
10	2,100	2,300	3,650	7,400
20	2,350	2,600	3,900	8,000
40	2,500	2,870	5,000	10,500
60	2,850	3,200	5,700	11,900
80	3,100	3,500	6,300	13,100

The above prices are reckoned on the basis of employing spiral construction ropes up to 20 tons capacity and locked coil ropes for 40 to 80 tons capacity, and represent the total cost of the plant erected. For lengths above 5 miles a proportional cost may be taken.

Working Costs per Day.

Length in Miles.	Capacity per Day in Tons.					
	50	100	200	400	800	1,000
	s. d.	s. d.	s. d.	s. d.	s. d.	s. d.
½	17 6	21 0	25 0	32 0	42 4	48 0
1	19 5	24 0	28 10	37 7	52 0	58 5
2	26 6	31 6	36 4	49 7	68 10	76 10
5	45 7	51 0	61 0	83 3	126 0	156 10

The above costs are inclusive of depreciation, but exclusive of the cost of driving, this being so different in each case, depending on difference of height between stations, etc., that it is impossible to standardise, and it must therefore be reckoned as an extra to the above for each separate plant.

See also Cost of Aerial Ropeways—Section XLV.

Fixed Clip Single Rope System.

This type of ropeway is only applicable for light capacities, and is used largely on plantations and for the transport of valuable ores, where comparatively small quantities are handled.

The carrier head, fig. 29, is permanently attached to the rope by means of a spring steel strap, and is designed in such a way that it can pass freely over trestle sheaves, under depression wheels and round the terminals, without being detached from the rope. As both rope and carriers are in constant motion, loading has to be done by hand, or by means of a travelling hopper, which is usually hung from overhead rails at the terminal. The terminals are extremely simple and

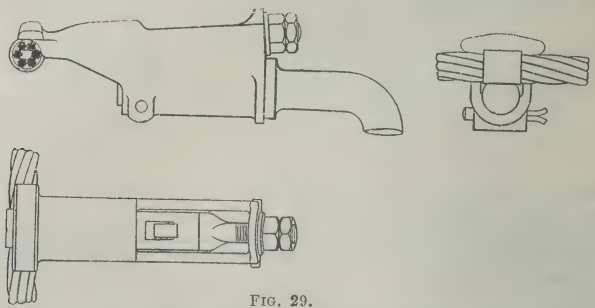

Fig. 29.

compact, as all shunt rails are done away with. The tension terminal is usually mounted on a trolley or on skids, the whole being movable by means of tension gear, to allow for stretch of rope, etc. Angles can be worked with the fixed clip system, but they should be preferably avoided, as they tend to produce excessive rope and gear wear at such places.

This type of line is run at a slow speed, namely, about 200 ft. per minute, and the only advantages it can claim are its simplicity, adaptability to steep grades, and its low prime cost when light capacities and moderate lengths have to be dealt with.

Jig-Back or To-and-Fro.

This type of ropeway is useful for short distances, and is operated with a pair of carriers that travel in reverse directions and are loaded or brought to rest alternatively at the opposite stations, but which do not pass round the terminals; it is, therefore, intermittent in its action, and the direction of travel is reversed after each journey. Where loads are to be carried which are heavy individually in relation to the capacity, and where the distance is short, the 'To-and-Fro System' is particularly applicable. A high carrier and rope velocity may be adopted during the run, especially where a clear span occurs between terminals, and where there are no intermediate trestles. These installations may be on the 'Monocable' or 'Bi-cable' principle, and in either case the moving rope is clamped to the carriers, and is not usually disconnected from them at the terminals.

It should be mentioned that, up to the present, the 'To-and-Fro' ropeway is the only system that is used for regular passenger traffic, as the carriers lend themselves to the adoption of a safety grip used in conjunction w th an auxiliary standing rope, but with such appliances these installations are very costly and present mechanical difficulties on lines of any length.

The following table, giving a rough idea of the capabilities of the various systems mentioned, shows the maximum lengths, capacities, and loads carried on various lines at present working or in course of construction:

System.	Present Maximum Lengths.	Present Maximum Hourly Capacity.	Present Maximum Individual Load.
	Yards.	Tons.	Tons.
Monocable .	80,196	200	$1\frac{1}{2}$
Bi-cable .	38,800	250	2
Fixed Clip .	2,330	8	4 cwts.
To-and-Fro .	1,850	Passengers' weight unknown.	17 tons.

Limitations of Types of Aerial Ropeways.

The *jig-back* type is the cheapest for short distances and a capacity of 8 to 12 tons per hour. Where the distance is considerable the loss of time in making the double journey between each load is too great, and where individual loads are heavy and the speed high too much time and energy is lost in starting and stopping.

The *monocable* type is suitable for a capacity up to 80 or 100 tons per hour where the grade of the rope is not steeper than 1 in $2\frac{1}{2}$ or 1 in $2\frac{3}{4}$. Where the rope grade would be steeper than this the boxhead clips would be liable to slip on the rope, and a bi-cable would have to be considered.

The *bi-cable* type is required for steep grades and large hourly capacity. It is evident from general principles that if the number and weight of the individual loads carried by a rope be gradually increased the tension and weight of the rope will have to be increased also, and at last a point will be reached when it is cheaper to fix the heavy main rope and use it for carrying purposes only and to provide an extra and lighter rope for hauling the loads. This point marks the natural transition from monocable to bi-cable.

CONVEYORS.

(Contributed by Professor John Goodman, M.Inst.C.E.)

Belt Conveyors.

For conveying materials continuously over long distances in a horizontal or inclined direction band conveyors are usually employed.

Single conveyors are made up to 48 ins. in width and over 1,000 ft. in length. They can be employed for handling almost any class of material excepting those which are hot or sticky.

Solid woven cotton belts are lowest in first cost, but they are not suitable for continuous or heavy duties, because sharp substances soon cut the fabric, and, moreover, they are not waterproof and are very sensitive to climatic changes, which cause them to stretch and contract abnormally.

Belts treated with bituminous solutions are partially waterproof and resist wear much better, but have the disadvantage of becoming hard, and, moreover, they will not accommodate themselves to the troughing idlers.

Balata belts, when manufactured with the true vegetable gum, are satisfactory for work in the open, as they resist damp better than any other type. The best quality belts are durable and easily conform to the troughing idlers.

Vulcanised rubber belts of best quality, although high in first cost, are the best and ultimately the cheapest for conveying hard, heavy, or sharp materials. The cotton duck, which forms the basis, provides great tensile strength, whilst the rubber cover is the best-known material for resisting wear and abrasion. The cover on the carrying side should be at least $\frac{1}{16}$ in. thick.

Woven wire belts of various types are used for special purposes, as, for example, colliery picking belts, where it is desired to extract dust during conveyance.

The following table, taken from the *Engineering Magazine*, March 1909, shows the comparative values of different belts and materials to resist abrasion. Sample strips were submitted to equal sand-blast, and the volume of material worn away was measured.

Rubber belt	1·0	Woven cotton belt (high grade)	6·5
Rolled steel bar	1·5	Stitched duck (,, ,,)	8·0
Cast iron	3·5	Woven cotton belt (low grade)	9·0 to 15·0
Balata belt	5·0		

The life which may be expected from a best quality rubber belt when handling coal is given by the following expression:

$$N = 3W_b^3L$$

where,

N = the number of tons which a rubber belt may be expected to convey before it is worn out;
L = length of conveyor centres in feet;
W_b = width of belt in inches.

When estimating the life of belts made of other materials, the result obtained by the above expression must be divided by the corresponding figure in the table.

Belt Joints.—For short conveyors, endless belts may be used, but owing to difficulty of fixing they are not recommended for long conveyors. The best fastener for heavy duty is made of thin steel plates in the form of a hinge, with pins of hard copper, and used in combination with leather safes for the ends of the belt. The fasteners are secured by copper rivets.

For short and medium conveyors a satisfactory joint can be made with 'Alligator' fasteners.

Intermediate Idlers usually consist of C.I. pulleys, 5 ins. or 6 ins. diameter, mounted on hollow shafts fixed in C.I. brackets and provided with grease lubricators.

Table I. gives the thickness of belt and pitch of idlers recommended.

TABLE I.

Width of Band.	Effective Cross-section of Material carried in Sq. Ft.		Largest Pieces Belt will carry.	Ply.	Pitch of Idlers.
Inches.	Flat.	Troughed.	Inches.		Ft. Ins. Ft. Ins.
12	0·04	0·09	2½ cubes	3 to 4	5 6 to 6 0
16	0·07	0·15	3½ ,,	4 ,, 5	5 0 ,, 6 0
18	0·09	0·19	4 ,,	4 ,, 5	4 6 ,, 5 6
20	0·12	0·22	5 ,,	4 ,, 6	4 6 ,, 5 6
24	0·16	0·34	6½ ,,	5 ,, 7	4 6 ,, 5 6
30	0·27	0·55	10 ,,	6 ,, 8	4 0 ,, 5 0

Terminal drums should have a crowned face 3 ins. wider than the belt, and the diameter should be not less than 5 times the number of plies in the belt.

The driven terminal should be mounted on a carriage controlled by weights to automatically take up any belt stretch.

The usual speeds of conveyors when handling coal, ore, broken stone, etc., are from 250 to 350 ft. per minute.

Belts are usually carried on troughing idlers for the above-mentioned materials.

Speed for handling grain, 400 ft. to 600 ft. per minute. Grain containing chaff should run at the lower speed.

Grain bands usually run on flat idlers.

The capacity in cubic feet per minute may be taken from Table I. by multiplying the effective cross-section of material carried by the speed of the belt in feet per minute.

The pitch of the idlers for the return belt should be from 9 ft. to 12 ft., according to the weight of the belt.

The power required depends on workmanship, diameter of idlers, and other factors.

If fully loaded and the conditions are good, the following expression gives the horse-power required for band conveyors:

$$\text{H.P.} = \frac{(0{\cdot}15B + 0{\cdot}07M)S + HW}{33{,}000},$$

where,

B = weight of belt in pounds; M = weight of material on belt at any time in pounds; S = speed in feet per minute; H = height elevated in feet; W = weight of material delivered per minute in pounds.

Steel Belt Conveyors.

(Steel Belt Conveyors Ltd.)

Conveyors employing a flexible steel band in lieu of the textile fabric or rubber belt are in use in Scandinavia, on the Continent generally, in Great Britain and Colonies, and U.S.A., for handling a wide variety of materials, and have proved particularly successful in the stone, ore, cement, brick, confectionery, and sugar trades.

The band itself consists of finest quality cold-rolled, hardened and tempered Swedish charcoal steel of the "Sandvik" brand, is of very dense texture, highly resistant to rust and corrosion, extremely durable, and has a tensile strength of about 80 tons per sq. in., equal to about 3 tons per inch of width of belt. It is rolled at present in widths up to 24 ins., one-piece lengths up to 300–350 ft., and thicknesses up to 1 mm. (about 0·04 in.), the longitudinal edges being rounded and smooth. It is joined by means of simple lap riveted or butt strap riveted joints which can be made in less than an hour. Small conveyors can have brazed or welded joints. The flexibility of the material is such that a coil of 300 ft. of 16 in. belt can be sent out packed in a case 2 ft. square by 1 ft. 6 ins. deep; it weighs approximately 2 lbs. per foot run.

Consequent upon its transverse stiffness and ability to be loaded over its full width without the edges yielding downwards, steel belt has a high carrying capacity, and in addition for many materials it can be troughed by means of skirting boards (the belt forming the bottom of a rectangular trough) which increases the capacity three to four times. Thus, an open 16 ins. belt at 200 ft. per minute could handle about 35 tons of coal per hour, and if troughed from 100 to 120. Under similar conditions an open belt could handle 100 tons of broken granite per hour on the basis of 150 lbs. per cubic ft.

The usual end-drums and intermediate supports at suitable intervals for the top and bottom strands are used. The supports usually consist of simple Roller Idler Sets, but for light duty conveyors the strands can slide on timber runners that have a smooth and graphited face.

The belt does not stretch, and the only variation that has to be provided for is due to expansion and contraction; the tension devices are therefore of the simplest, and for a conveyor not exceeding 120 ft. in length working at normal temperature the sag in the bottom strand is sufficient to provide for all give and take required. Other than that a simple tension frame is employed, operated by either balance weight and rope, balance weight and levers, or springs.

Material up to a temperature of 200° F. may be conveyed without unduly affecting the belt.

Drag Bar or Scraper Conveyors.

These take the form of a wide chain travelling in a fixed trough, the material being dragged along by the chain bars. Considerable horse-power is required to drive this type, on account of the friction of the material and chain in the trough. Even with this fault the type is largely used where simplicity and few working parts are of premier importance. Examples are the 'Blackett' Conveyor, used at the coal face in collieries. The 'Bennis' Conveyor, much used in boiler stoking plants, and the 'Jenkins' 'D B' Patent Conveyor, which is principally used in gasworks for conveying hot or cold coke. It is also used for handling ashes, gravel, etc.

The conditions met with in handling coke are probably more severe than with any other material. First, because the coke reaches the trough at a temperature up to 1,700° F.; and, secondly, the coke is of a hard cutting nature, and contains a quantity of fine particles which work into the joints. Lubricants cannot be used, and finally the conveyor is in use night and day all the year round. Yet these chains frequently have a life of from three to four years, and convey up to 130,000 tons of material.

The 'DB' Conveyor consists of a special double chain connected together with cross-bars integral with special links at intervals of 2 ft. 1½ ins., and in widths from 12 ins. to 36 ins. or more. The detail of the chain is shown in fig. 30, and as used with a trough for hot coke, fig. 31.

It will be noticed that special short links are used alternately with long narrow links. Only the short links bear on the trough. The usual speed of such a conveyor is from 40 to 50 ft. per minute.

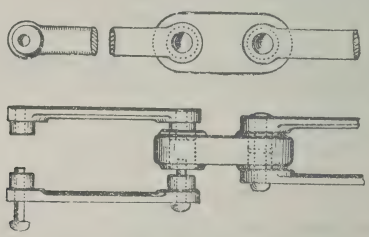

FIG. 30.

A trough 2 ft. 6 ins. wide, 7 ins. deep, will convey 20 tons of coke per hour and consume about 1 h.p. per 33 ft. of horizontal length.

The conveyor will work satisfactorily on inclines up to 33°, and with special cross-bars up to 70°.

The longest single conveyor installed is 350 ft. long, on the horizontal, with the addition of 60 ft. inclined at 30°.

The power required to drive this conveyor fully loaded is 14 b.h.p.

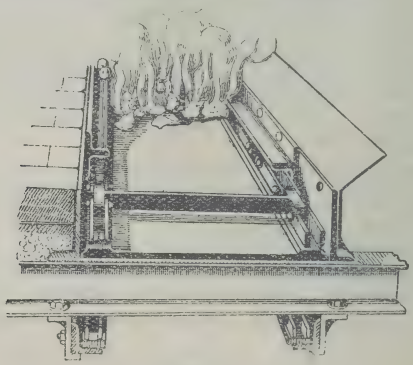

FIG. 31.

Scraper Conveyors are mostly used for handling coal when it is desired to discharge at short intervals and when dealing with quantities of from 20 to 40 tons per hour up to a maximum length of about 200 ft. For lengths beyond this it is better to use a Pushplate Conveyor, on account of the power required to drive being so much less.

The longest 'DB' Scraper Conveyor installed is 231 ft. long, dealing with 40 tons per hour, and requires 16 h.p. when fully loaded.

PUSHPLATE CONVEYORS.

These are in general use for conveying and delivering coal into storage hoppers. Conveyors of this type are superior to any other when it is desired to deliver coal at many intermediate points. For this purpose, outlets, with slide doors, are arranged in the trough where

desired. Generally the chain is provided with special attachment links at intervals, which carry M.S. plates and axles fitted with C.I. rollers, and grease lubricators. The plates are kept clear of the trough so as to avoid any noise when working.

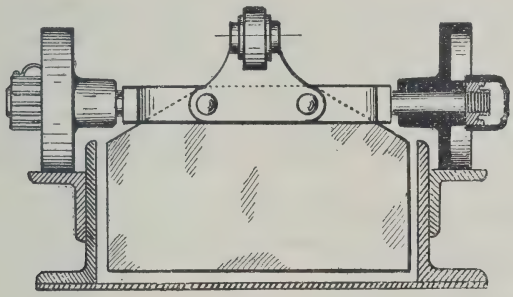

FIG. 32.

The usual speed is 100 to 120 ft. per minute, and as there is only the sliding friction between the coal and the trough the power taken is not excessive.

A typical Pushplate Conveyor is shown in section by fig. 32. For dealing with 25 tons of coal per hour the trough would be 15 ins. wide and 6 ins. deep. A single chain would be fitted with pushplates 17 ins. apart. The rollers would be grease lubricated, 6 ins. diameter and 4 ft. 3 ins. apart. A conveyor of this type, 250 ft. long, running at 120 ft. per minute, requires 5 b.h.p. to run empty, and 7 b.h.p. to run fully loaded.

TABLE II.—PUSHPLATE CONVEYOR FOR COAL.

Size and Capacity in Tons per Hour.			
Width of Trough.	Pitch of Pushplates.	Depth of Trough.	Tons of Coal per Hour.
Inches.	Feet.	Inches.	
12	1·5	6	20
15	1·5	6	28
18	1·5	6	35
24	1·5	6	45

The following gives the horse-power of scraper and pushplate conveyors:

$$\text{H.P.} = \frac{KS(M + G)}{33{,}000},$$

where,

K = constant, say 0·37 for scraper and 0·13 for pushplate conveyor with rollers; S = speed in feet per minute; M = weight of material on conveyor at any one time in pounds; G = weight of moving parts of chain in pounds.

The friction of the driving gear must be added to the above.

GRAVITY BUCKET CONVEYORS.

This type of conveyor is unique in the sense that one unit can transport vertically, horizontally, and at any intermediate angle, and for this reason they are much used in power-stations for elevating and storing coal in overhead bunkers.

The principle employed is a series of buckets mounted on steel spindles, which are connected to two endless chains at regular intervals, the ends of the spindles are provided with C.I. grease-lubricated rollers for the purpose of travelling on horizontal rails or between inclined guides.

The buckets are suspended above their centre of gravity in such a manner that they always remain in an upright position until they are tilted by cams or levers provided for the purpose.

The corner guides for changing the direction of the chain should preferably consist of two sprocket wheels large enough in diameter to allow the buckets to swing clear of the shaft; one wheel should be keyed in place, and the other allowed to turn freely on the shaft between collars, so as to rectify any trouble that may arise should one chain stretch more than the other.

As the buckets are mounted on the chains with a space of an inch or more between, it is necessary to provide a special 'feeding device' for filling the buckets. Several types are in use, but probably the most popular is in the form of a drum having a circumference equal to at least five pitches of buckets. Outlets are arranged corresponding with the pitch, with blank plate between.

The drum is rotated by direct gear with the chain, and the material is fed through the centre. The blank plates prevent the material spilling between the buckets.

It is sometimes necessary to feed buckets at several points; in this case the filler is provided with travelling wheels to run on separate rails, and is rotated by a large sprocket wheel which engages with one of the bucket chains.

TABLE III.—SIZE AND CAPACITY OF G.B. BUCKET CONVEYORS FOR COAL.

Tons per Hour.	Pitch of Buckets.	Buckets.			Speed.
		Length.	Width.	Depth	
	Inches.	Inches.	Inches.	Inches.	45 ft. per minute
30	21	22	16	9	
40	27	24	16	10	" "
50	27	24	20	11	" "
60	27	24	22	11	" "
100	27	26	30	12	" "

The following gives the horse-power required for gravity bucket conveyors:

$$\text{H.P.} = \frac{CH}{884} + \frac{S(W_m + W_c)}{180}$$

where,

C = capacity in tons per hour; H = height to be lifted in feet; S = speed in feet per minute; W_m = total weight of moving parts of conveyor in tons; W_c = total weight of coal in conveyor in tons.

Add for friction of gearing and motive power.

See also *Proceedings of the Inst. Mech. Engrs.*, No. 2, 1921.

PNEUMATIC CONVEYORS.

See "The Nuvako Pneumatic Conveying System"; *Engineering*, Dec. 9, 1927.

WATER CONVEYOR.

W. J. Jenkins & Co., Ltd., Retford.

In the Le Fleuve system of handling hot coke in Gas Works, the material, on being discharged from the retorts, is directed by means of a shoot to a concrete trough A, along which a stream of water is flowing (fig. 33.) When the red-hot coke comes in contact with the water, steam is given off in such quantities as to lift the coke and thereby to prevent it coming into contact with the bottom of the trough, thus the frictional resistance to motion is due to the flow of water, and not to dragging the coke along the trough. The coke and water are delivered to perforated trays on a short inclined conveyor, which allows the water to escape. Owing to the residual heat of the coke, the moisture carried over is evaporated, thus leaving the coke ideally quenched when delivered by the tray conveyor.

'LE FLEUVE' WATER CONVEYOR

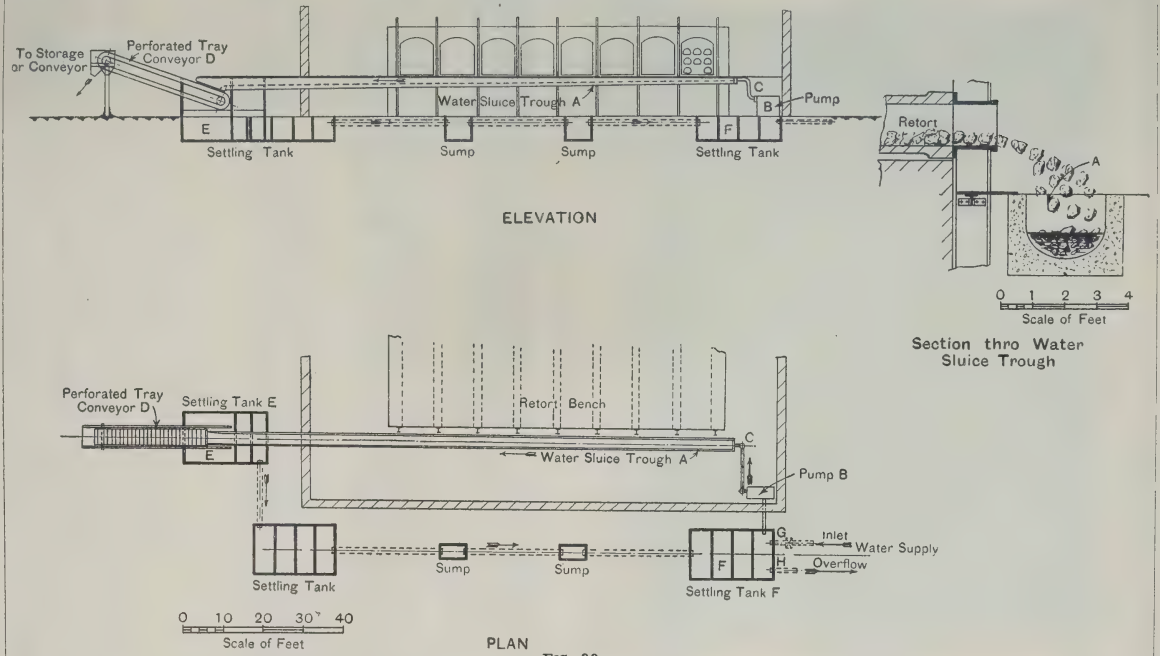

FIG. 33

The system is simplicity itself, and highly efficient. The coke is gently handled throughout consequently the breakage is reduced to a minimum.

When there is an ample supply of water it can, after use, be discharged into any convenient drain, after the solid matter has settled in suitable chambers E F, but when the supply of water is limited, it can be used over and over again by means of a circulating pump.

(*John Goodman.*)

Brake Linings.

Ferodo Applied to Brakes.

(*Ferodo, Ltd., Chapel-en-le-Frith.*)

Present-day high speeds and heavy loads require powerful and reliable brakes, these being especially necessary for modern lifting machinery. The friction coefficients of wood, leather, and metal are comparatively low, the values usually falling with heat and general working conditions; with the Ferodo lining on brakes (block, band, or disc type) the coefficient of friction increases as the temperature increases, the action is smooth, reliable and powerful, and reduces the wear and tear on the drums and gears. Ferodo fabric is readily fixed to a steel band, metal, or wood blocks.

For description of, and tests with, this material, see page 897.

Chekko Brake and Clutch Linings.

(*Cresswell's Asbestos Co., Ltd., Wellington Mills, Bradford.*)

These linings are made from 100 per cent. pure long asbestos fibre woven into brass wire in one solid piece; they are made in sheet from 2 in. to 12 in. wide, and in thickness varying from $\frac{3}{8}$ in. to $\frac{1}{4}$ in. The sheeting when cut to the required size is fastened to wood foundation blocks by means of counter-sunk brass screws, which screw into metal nuts, the latter lying in slots cut in the wood. In the case of a steel band being lined with the material, the screws pass through the band and screw into nuts on the outside of the band, or aluminium rivets may be used for the purpose. See also p. 897.

Notes on Fabric Linings.

A most important point to observe in regard to the use of fabric linings is that the blocks to be lined are first worn down so that they will make a true arc of contact, also that the fabric lining after being fitted is clear of the brake path at every point of its surface when not in action. In band-type brakes the same observations are essential, and an arrangement should be fitted whereby the top half of the band is kept well clear of the brake path by suitably arranged and powerful springs when idle.

Brake paths which are out of truth or have undue lateral play should be corrected, and the paths should be as smooth as possible. Given these conditions, experience proves that fabric linings are cheaper in the end as regards mere cost than materials which may cost little in themselves and are only costly in labour and renewal. In addition to the saving effected, there is improved efficiency, greater power, much sweeter action when engaging and disengaging, and greater durability.

In all brake paths the abutting edges should be tapered back a good 2 ins. to eliminate all possibility of any edge rising above the circumference of the path.

The manufacturers generally send out carefully printed instructions regarding fixing and applying, also as regards the correct material to use, and a little care and thought are all that are required to eliminate the possibility of failure.

Magnetic Separators.

(*The Rapid Magnetting Machine Co., Ltd., Birmingham.*)

Magnetic separators are made for removing iron as an impurity, recovering for its value, and preventing damage to crushing and other machinery.

One of the latest applications of magnetic separation, fig. 34, is for the recovery of iron (largely in the form of empty tins, used for canned food) from house refuse, *before passing to the destructor.*

The Rapid Magnetting Machine Co., Ltd., Birmingham, have taken out a patent for use in conjunction with the revolving screen used for removal of the dust as a preliminary operation.

The invention primarily consists of a very powerful electro-magnet, partly surrounding the ' delivery-off ' end of the screen. As the iron reaches the magnetic field the metal is drawn to

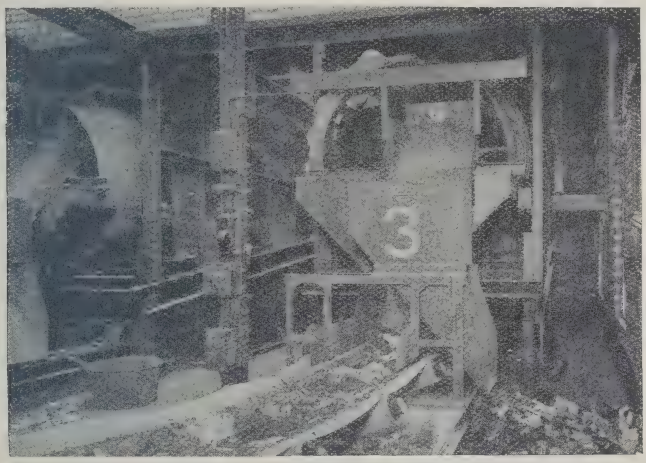

FIG. 34.

the inside surface of the screen and carried up to the vertical centre, where it is automatically released without the aid of mechanical cut-outs, falling into a shoot which diverts it to the side of the apparatus.

A common use of a magnetic separator is for the separation of iron from non-ferrous metals.

SECTION XIX

(Revised and amplified by Professor Dempster Smith, M.B.E., M.Sc.Tech., M.I.Mech.E.)

PART I

BELTING—ROPE DRIVING—CLUTCHES.

BELTING.

Power Transmitted by Belting.

The following formula gives the power transmitted by any belt :—

$$H = \frac{(T - t)v}{33{,}000},$$

where,

H = actual horse-power transmitted ; T = tension in lbs. on the pulling side of the belt; t = tension in lbs. on the slack side of the belt ; v = speed of belt in feet per minute.

When a belt is doing its full work, T will be the greatest safe working tension that the belt will stand ; this is about 90 lbs. per inch of width for singles (more accurately 60 lbs. to 120 lbs., according to the thickness of the leather), and about 150 lbs. for doubles (135 lbs. for light and 160 lbs. for heavy doubles). In order that the belt shall do as much as possible, t must bear such a ratio to T that the belt just does not slip over the pulleys. In practice t varies from $\frac{1}{3}$ to $\frac{2}{3}$ of T, depending on the character of the surfaces of the belt and pulley, and on the fraction of the circumference of the pulley embraced by the belt ; $\frac{1}{2}$ of T will be a safe average value for t ; so that $T - t$ will be on the average 45 lbs. for singles and 75 lbs. for doubles for every inch of width ; hence the following rule for finding the power that any given belt should transmit :—

Multiply the width of the belt in inches by 45 if single, by 75 if double ; multiply this again by the speed in feet per minute, and divide by 33,000 ; the quotient will be the number of actual horse-power the belt will transmit.

EXAMPLE 1.—Required the horse-power which a 5-in. single belt, running at 1,000 feet per minute, will transmit.

$$5 \times 45 \times 1{,}000 \div 33{,}000 = 7 \text{ horse-power (nearly).}$$

EXAMPLE 2.—What power can be transmitted by a 12-in. double, running at 1,500 feet per minute ?

$$12 \times 75 \times 1{,}500 \div 33{,}000 = 41 \text{ horse-power (nearly).}$$

EXAMPLE 3.—An example of the reverse kind : What width must a belt be to transmit 20 horse-power, the belt running at a speed of 2,500 feet per minute ?

$$(20 \times 33{,}000) \div (2{,}500 \times 45) = 6 \text{ ins. nearly, if single.}$$
$$(20 \times 33{,}000) \div (2{,}500 \times 75) = 3\tfrac{1}{4} \text{ ins., about, if double.}$$

The values given in the table are more accurately calculated, and hence do not exactly agree with the above examples.

The size of the pulleys or the number of square inches of contact between belt and pulleys has no effect on the power transmitted ; that is to say, the same belt will have just as much grip, other things being equal, on 1-foot pulleys as on 4-foot pulleys. The fraction of the circumference of the pulley embraced by the belt, however, has an important effect on the friction between the two ; that is to say, if the belt is in contact with the pulley for more than half the circumference of the latter it will get a better grip, and will therefore transmit more power than if in contact for less than half the circumference ; hence the desirability, where possible, of making the pulling half of the belt the lower one, so that the slack upper side may sag down and lap further round the pulley.

The following table gives the number of horse-power which belts of various sizes should transmit. Allowance has been made for the loss of power at high speeds, due to the centrifugal force of the belt. This loss is negligible at low speeds, but increases with the velocity, amounting

to about 10 per cent. at a speed of 3,000 feet per minute, and about 30 per cent. at 5,000 feet per minute; no advantage is gained by running a belt faster than 4,000 or 5,000 feet per minute.

Under very good conditions of working, belting will transmit up to 1½ times the amounts given in the following table without being overstrained. (*Richardson.*)

TABLE SHOWING HORSE-POWER TRANSMITTED BY LEATHER BELTS UNDER AVERAGE WORKING CONDITIONS.

Speed of Belt. Ft. per Min.	Width of 'Single Thickness' Belts (ins.).									
	1	2	3	4	5	6	7	8	9	10
500	0·67	1·4	2·2	3	3·7	4·5	5·2	5·9	6·7	7·4

3,000	3·8	8	12·3	16·8	21	25	29·5	33·5	38	42
3,500	4·3	9·2	14	19·2	24	29	34	38·5	43	48
4,000	4·8	10·4	16	21·8	27·2	32·5	38	43·5	49	54·2
4,500	5·4	11·4	17·5	24	30	36	42	48	54	60
5,000	6·0	12·5	19·3	26·5	33	40	46	53	60	66

Light 'double thickness' belts will transmit 30 per cent. more power than that given in the above table.

For ordinary 'double thickness' belts the values given in the table may be increased 50 per cent., whilst for extra heavy 'double thickness' belts the values given in the table may be increased 70 per cent.

For intermediate speeds, and widths of belt, the h.p. transmitted is proportional to the speed or width of belt.

DICK'S ORIGINAL BALATA BELTING.

Table showing the horse-power which each inch of width of Dick belting, from 3-ply to 10-ply, will transmit at the speeds given.

4,250	5·15	7·72	10·30	12·88	15·45	18·02	20·60	23·17
4,500	5·45	8·18	10·90	13·64	16·36	19·08	21·80	24·54
4,750	5·75	8·63	11·51	14·40	17·28	20·14	23·02	25·91
5,000	6·06	9·08	12·12	15·16	18·20	21·20	24·24	27·28

N.B.—These calculations, which are based on the most conservative lines, are given for ordinary loads over pulleys of proper diameters; anything abnormal in a drive should be taken into account in specifying the belt required.

The following table is the 'Dick Equivalent' of the best quality of leather belt :—

Dick belt 3-ply equals 14 ozs. single leather.
" 4 " " 18 ozs. "
" 5 " " 26–28 ozs. double leather (up to 12 ins. wide).
" 6 " " 30–32 ozs. double leather (over 12 ins. wide).

(*R. & J. Dick, Ltd.*)

German Practice.

In Germany it is usual to allow a higher effective tension per inch of belt width with increase in the diameter of pulley and speed. The table given below is compiled by Herr C. Otto Gehrckens and represents his practice for the past few years :—

Safe Effective Tension per Inch of Width (*Gehrckens*).

Diam. of Pulley.	Velocity Feet per Min.

NOTE.—This table may be thoroughly relied upon for all ordinary conditions of working The results of tests made by Chas. Hopkinson, M.Inst.C.E., M.Inst.M.E., B.Sc., show that the 'Camel' Brand belt working under favourable conditions will safely transmit double the horse-power given in the above table.

Cross Section of Belts.

The following table shows what area of cross section of leather belt is needed to give various horse-powers, with various arcs of contact on cast-iron pulleys, at a belt speed of 3,000 feet per minute, the fastenings being single leather lacings. From it, having decided on the thickness. the width may be determined, or *vice versa*, by simple division:

Arc Contact.	Horse-powers.									
	5	10	15	20	25	30	35	40	45	50
Deg.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.	Sq. in.

Belt Tension.

To find out whether the force carried by a belt is more than should be properly put upon it, or upon its fastening, we must know how much the arc of contact is, and what the tension on both the tight and the slack folds. The greatest tension upon it is that in the tight fold or side; and this is equal to that on the slack side plus the pull which the belt gives to the pulley or which the pulley gives to it. The greater the arc of contact, the greater the ratio between the tight and the slack side, and the less the tension will be upon the belt and its fastening to transmit a given power at a steady speed. Thus, if we have a pull of 10,000 lbs. necessary to carry a certain horse-power, when the arc of contact of the belt on the pulley is 90°, that means

CAMEL HAIR BELTING

The World's Greatest Power transmitter

CAMEL-HAIR BELTING
REGISTERED TRADE MARK

OVER 100,000,000 feet of Camel Hair Belting, varying in width from 2 to 60 inches, have been supplied to world-wide users since the date of its invention now **57 Years Ago.**

Camel Hair Belting gives to the user not only absolute efficiency in all attributes determining effective power transmission, but adds thereto the greatest economy in annual expenditure for upkeep.

that the ratio between the tension on the tight side and that on the slack side is 1·874; in other words, for every pound upon the slack side there will be 1·874 lbs. on the tight side; and if the difference between the tensions on the slack and the tight sides be 1,000 lbs., it will be necessary to have 1,000 ÷ 0·874 = 1,144 lbs. tension on the slack fold, and 2,144 on the tight one. (These figures apply to leather belts in good condition upon cast-iron pulleys, also in good condition.) The following table shows the ratio between the tension and transmitted pull for various arcs of contact from 30° to 300° :—

TABLE OF GREATEST TENSION ON BELTS.

Degrees of Arc . .	30	45	60	75	90	105	120	135
Ratio between tension and transmitted pull .	5·29	3·71	2·92	2·45	2·14	1·93	1·77	1·64
Degrees of Arc . .	150	165	180	195	210	240	270	300
Ratio between tension and transmitted pull .	1·54	1·47	1·40	1·35	1·30	1·23	1·18	1·14

EXAMPLE.—If it takes a pull of 300 lbs. to carry a given horse-power when the arc of contact is 195°, then the tension upon the tight side will be 1·35 × 300 lbs., or 405 lbs. Expressing results in horse-power instead of pounds pull, suppose that it is necessary to carry 175 horse-power with a belt running 2,000 feet per minute, and having 210° arc of contact; then the pull on the pulley will be 33,000 × 175 ÷ 2,000 = 2,887 lbs.; and the greatest tension upon the belt will be 2,887 × 1·3 = 3,753 lbs.

For double leather main belts,

$$\text{H.P.} = \frac{80\ W\ V}{33{,}000}$$

where

W = breadth in inches; V = velocity in feet per minute.

General Rules for Belts.

(1.)

A good all-round rule, and one easily remembered for belt calculations, is that 1 ft. per minute of belt speed per inch of width of belt is safely equal to the transmission of 1 watt of electrical energy. If we therefore multiply the belt speed in feet per minute by the width in inches, the result will be the total energy in watts; and if we divide the result by 1,000, the energy is obtained in kilo-watts, which energy the band may be relied upon to transmit without any undue tension being brought upon any part of the belt or excessive friction in any part of the machinery. These data, however, only apply to single leather belting or to woven belting of a similar thickness. If a light double band be employed, then 25 per cent. more energy may be calculated upon; or for heavy double leather belting as much as 60 per cent. more may be added. The great advantage for this method of calculation is that it fixes a constant for working tensions, so that the working tension becomes directly proportional to the width in inches, this constant being 44·24 lbs. pull per inch width of belt. If we wish, therefore, to know the difference in pounds pull on the tight and on the slack side of any belt, all that is necessary is to divide the total output of the machine in watts by the velocity of the belt in feet per minute, and multiply the result by 44·24, and the product will be the extra pull in pounds on the tight over the slack side. (*R. Berry.*)

(2.)

One horse-power will be transmitted by a single thickness belt 1 inch wide running at the rate of 1,000 feet per minute.

A belt $\frac{3}{10}$ths of a square inch section will transmit 1 horse-power at the foregoing rate.

Tension on belt by either of these rules will be 33 lbs. per inch of width and 165 lbs. per square inch of section.

With belts in good working order the frictional hold on the pulleys is about 58 per cent. of the pressure of the belt on the surface of the pulley as a maximum, and about 42 per cent. under ordinary atmospheric conditions.

It is safe to reckon that a double belt will do half as much work again as a single one.

Belting made of Helvetia leather is much stronger and will bear a heavier load than that made from ordinary tanned leather.

A double belt is more serviceable upon pulleys of large than upon those of small diameter, and should not be used upon pulleys whose diameters are less than about 3 times the width of the belt, unless the belt width exceeds about 4 ins.

Rubber belts will transmit from 25 to 40 per cent. more power per given arc of contact than leather belts. They should not be used in situations where they will be subject to a temperature of over about 90° F.

The average weight of a good four-ply rubber belt 7 ins. wide is 16 ozs. per linear foot. The best rubber belting is made with 32 ozs. duck, and then weighs 20 ozs. per linear foot.

It is a common error among mechanics and owners of factories to make the face of their pulleys narrow, in order to economise on the first cost of belting; but this false economy seldom decreases the cost of the machinery, and only saves a trifle in the first cost of belting. The small amount saved is soon lost by the stopping of machinery caused by the slipping of belts, strain on the shafting, increased friction (requiring additional driving power), and rapid destruction of the belts themselves. Were pulleys made of a proper size and width and face, and belts of proper width run with the *grain* side of leather to the pulley, a considerable saving of coal might be effected annually and an immense amount of trouble avoided.

Leather belts with grain side to pulley can drive 34 per cent. more than flesh side.

(3.)

To find the diameter of driving pulley.—Multiply the diameter of the driven by the number of revolutions it should make, and divide the product by the number of revolutions of the driver.

To find the diameter of driven.—Multiply the diameter of the driver by its number of revolutions, and divide the product by the number of revolutions of the driven.

To find the number of revolutions of the driven.—Multiply the diameter of the driver by its number of revolutions, and divide by the diameter of the driven.

To find the horse-power of a pulley.—Multiply the circumference of the pulley (feet) by the revolutions per minute, and the product thus obtained by the width of the belt, and divide the result by 600. The quotient will be the horse-power.

Length of Belts.

(1.)

(Not crossed.)

RULE.—Add the diameter of the two pulleys together, divide the result by 2, and multiply the quotient by $3\frac{1}{7}$; then add this product to twice the distance between the centres of the shafts; the result is approximately the length required.

(Crossed.)

RULE.—Mark off by lines the pulleys, set at their proper distance apar (either full size or to scale), and measure the length of the side of the belt, supposing the belt to envelop one-half the circumference only of each pulley, and add to this one-half the circumference of each pulley. If there is a great difference between the relative diameters of the pulleys, and the distance apart of the shafts is unusually small, the length of the straight sides of the belt should be measured, and the arcs of contact around the pulleys stepped around by compasses, the set of the latter being not more than about one-tenth the circumference of the pulley.

In the case of both running horizontally, the upper half of the belt should be the driving side.

(2.)

(Auguste Esnoul, A.C.G.I.)

Let X = distance between centres of pulleys; D and d = respective diameters * of pulleys; C and c = respective circumferences; P = a parameter equal to D − d for open, and to D + d for crossed belts, exclusive of lap for jointing; L = length of belt, then

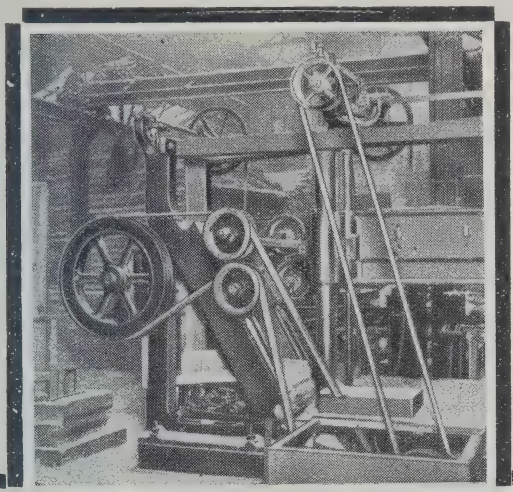
$$L = \tfrac{1}{2}(C + c) + 4X - \sqrt{4X^2 - P^2},$$

with an approximation such that the relative error is less than 1 in 1,000 for values of the ratio $\frac{X}{P}$ greater than or equal to 1·5; the relative error is about $\frac{1}{2}$ per cent. when $\frac{X}{P} = 1$.

For exact results, $L = \frac{1}{2}(C + c) + KX$, for both open and crossed belts; and $L = mX$ for crossed belts, where K and m are coefficients, tabulated herewith for the various values of the ratio $\frac{X}{P}$.

---

* Strictly speaking, D and d should be the theoretical diameters—that is to say, actual diameters plus thickness of belt.



HENDRYS'

LAMINATED BELTING

For Phenomenal Flexibility, Smooth, Vibrationless Running, Exceptional Durability and Maximum Power Transmission

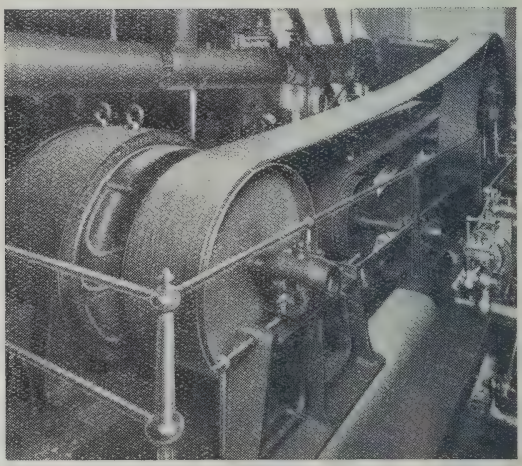
Sole Manufacturers

JAMES HENDRY LTD.

MAIN STREET, BRIDGETON, GLASGOW.

F. 860

ANY LENGTH—ANY WIDTH



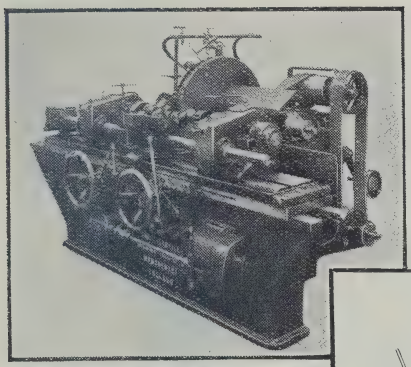
and up to 1" THICKNESS

Only the finest selected leather is used in the manufacture of Hendrys' Belting. Made under a special patent process, the leather is built up to the required size in a single ply from a single tested strand of solid leather. Efficient driving over pulleys is guaranteed with, in many cases, only half the usual width of belting. For smooth, vibrationless running always specify Hendrys'.

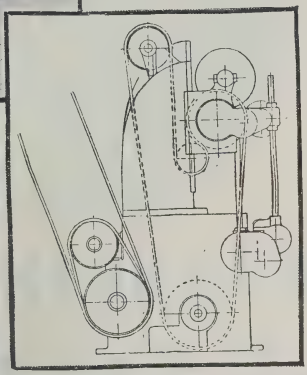
HENDRYS'

LAMINATED BELTING

JAMES HENDRY, LTD., BRIDGETON, GLASGOW



FOR EFFICIENT SHORT CENTRE TRANSMISSION



Maximum power transmission between long and short centres. No metal fasteners or cemented joints. The special construction of Hendry Belts ensures extraordinary flexibility and phenomenal grip

The illustration above is of Kearns' Horizontal Boring, Facing, Milling and Drilling Machine. Diagram below shows belt lay-out. All are Hendrys' No. 3×5″.

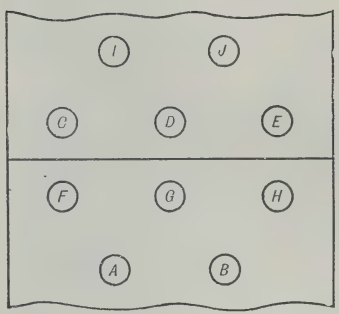

FIG. 1.

Jointing Belts.

LACED BUTT JOINT.

For belts about 3 ins. wide and over, the holes C, D, E, and F, G, H, should be about 1 in. apart and $\frac{5}{8}$ in. from the line of joint; A, B, and I, J should be about $\frac{1}{2}$ in. behind C, D, E, and F, G, H, respectively.

The sizes of the holes should be as follows:

Width of belt up to 4 ins.	Size of punched hole,	$\frac{1}{4}$ in.
„ „ from 4 to 8 ins.	„ „	$\frac{5}{16}$ in.
„ „ „ 8 ins. upwards	„ „	$\frac{3}{8}$ in.

WIDTH OF LACES.

Width of belt 24 ins. and over.	Width of lace,	$\frac{1}{2}$ in.
„ „ 6 to 24 ins.	„ „	$\frac{3}{8}$ in.
„ „ 2 to 4 ins.	„ „	$\frac{5}{16}$ in.
„ „ 2 ins. and less	„ „	$\frac{1}{4}$ in.

A square should always be used in cutting the ends of a belt preparatory to joining them, to ensure that they will be cut at a true right angle to the centre line of the belt. If a square is not employed, one or both ends are likely to be cut uneven or irregular, and these conditions cause the belt to slip from side to side of the pulley and impose irregular strains on the belt fibres, which no belt can endure indefinitely. Belts of widths up to about 18 ins. can be cut sufficiently true by holding one leg of the square against one side of the belt, having the other leg project across the belt, and then cutting along the edge of the latter with a sharp knife held perpendicular to the belt. The knife blade should be made wet occasionally to make it cut easily.

The ends of wide belts are difficult to cut square on account of slight variations in their widths and because the sides may not be exactly parallel; satisfactory results may be assured by the following method: At any point on the belt near where it is to be cut, measure across and find the centre, then at a point 2 or 3 ft. back from these dimensions, locate the centre again, and between these two points draw a clean sharp line. Next, by holding one leg of a square against the centre line just made, trim off one-half of the end of the belt by cutting along the other leg. By laying the square on the other side of the centre line, the other half of the belt can be cut. The square should be held firmly in position while cutting the belt, and if two small nails are driven in the belt on the centre line, they will help to keep the square from slipping.

Joining Thin Belts.

Place two ends of belt together, with edges fair one with the other, and make with an awl a row of holes, at *a*, through both ends. Then take about half a yard of strong twine, and draw half the length through the first hole; then pass each end of the twine through the second hole, one to the right and the other to the left, and draw both tight at the same time,

Fig. 2.

and so on until the last hole is reached, when one end only of the twine is passed through. The two ends of the twine are then knotted together, and the excess cut off.

Lap Joints.

Fig. 3.

Cut down overlap to a plain bevel, cement surfaces together, and insert small taper wooden pegs, such as are used for boot and shoe manufacture. This is the strongest form of joint that can be made.

Length of Lap.

Width of single belt, in inches .	1 to 4½	5	6 to 8	9	10 to 14	15 to 24
Length of lap, in inches . . .	4½	5	6	6½	7	8

All double belts should have a 6-inch lap at least.

Cement for Belt Joints.

Equal parts of good glue and American isinglass; place the material in a glue pot and add sufficient water to cover the whole. Let the mixture soak ten hours, then bring the whole to a boiling heat, and add pure tannin until the whole appears like the white of an egg. Apply warm. Buff the grain of the leather where it is to be cemented, keep the joint surfaces pressed firmly together, let the joint dry for a few hours, and the belt will be ready for use.

(*Railway and Locomotive Engineer.*)

To Find Length in Feet of Belt in a Roll.

From outside diameter (D) deduct inside diameter (*d*), multiply by number of turns (*n*) and by 0·262.

Example.—D = 12 ins., *d* = 4 ins., *n* = 16 ins. Length = (12 − 4) × 16 × 0·262 = 33·5 ft.

Belt Dressings.

'Gripwell' Belting Syrup (*Asbestos Cement Building Products, Ld., Trafford Park, Manchester*) is particularly suited for fast and loose drives or shock drives, to prevent slip; the dressing is applied hot, so as to penetrate the belt freely.

Oiling and Greasing Leather Belts.

When the belt is pliable, and only dry and husky, apply blood-warm tallow, and dry in by heat of fire or sun. The addition of resin to the tallow for belts used in wet places is advantageous. Belts which have become hard and dry should have an application of neatsfoot or cod-liver oil mixed with a *small* quantity of resin.

Suggestions to Belt Users.

In order to obtain a given amount of power, it is better to use a narrow belt running at a high speed than a wide belt running at a low speed.

If possible, use a belt speed of about 3,000 feet per minute for smaller powers, and about 4,000 feet per minute for high powers. Thrashing machine belts run at about 2,200 feet per minute, and this is the usual speed for agricultural machines.

Use a pulley that is wide enough, so that a small amount of irregularity in the belt does not make it run off. Allow at least ½ in. on machine pulleys and 1 in. or more on countershaft and lineshaft pulleys. Use crowned pulleys wherever possible.

If possible, use a horizontal belt with large centre distances and with the pulling side at the bottom. In a horizontal drive, the slack side of the belt at the top of the drive increases the belt contact.

When using a vertical belt, do not have more centre distance than is absolutely necessary, because the weight of the belt reduces the efficiency of the drive.

Avoid crossed belts on short centre distances. Avoid the crossing of wide belts. If it is necessary to cross belts, see to it that the rubbing of the belt surfaces does not have a tendency to open up the laps.

Keep belts flexible and as clean as possible. Lubricating oil should not be allowed to remain on a belt, but should be removed by applying powdered chalk.

Do not use belt dressing containing mineral oils or resins.

Double belts should not be used on small pulleys.

Hints on Belt Driving.*

(John Tullis & Son, Ltd., St. Ann's Works, Glasgow.)

Pulleys having a high convexity prevent the belt from grasping its work. One-sixteenth of an inch is sufficient convexity for pulleys 6 ins. wide and under; $\frac{3}{32}$ of an inch is enough for pulleys over 12 ins. wide.

By compounding two single or double belts the gain in horse-power is close on 100 per cent.

By compounding three single or double belts the gain in horse-power will be close on 200 per cent.

Double belts should never be run on pulleys of small diameter. Compound single belts give much better results as regards power, longer life, and less cost.

Compound belts save the cost of wide pulleys as well as the room of wide pulley space.

Every inch in width of good double leather belting, travelling at 500 ft. per minute, while working on pulleys 24 ins. diameter, will transmit one horse-power, provided the arc of contact is 180 degrees.

Every inch in width of good single leather belting, travelling at 800 ft. per minute, while working on pulleys 24 ins. diameter, will transmit one horse-power, provided the arc of contact is 180 degrees.

A comfortable working strain for a single belt is about 50 lbs. for every inch of breadth, and for a double belt 80 lbs.

A belt running with the soft flesh side next the pulley will wear longest, because it is working according to the natural growth of the hide.

When driving on pulleys of 4 ins. diameter and under, the belt ought to be barely $\frac{1}{8}$ in. thick. On pulleys 4½ ins. to 8 ins. diameter the belt should be about $\frac{5}{32}$ in. thick. On pulleys 8½ ins. to 12 ins. diameter the belt should be about $\frac{3}{16}$ in. thick. On pulleys 12½ ins. to 18 ins. diameter the belt ought to be barely ¼ in. thick. On any diameter above 18 ins. heavy leather can be used with profit.

If the slack side of a main driving belt runs in wave form it is certain that the engine is getting more steam on one side of the piston than on the other. This unsteadiness is transmitted to all the working belts in the factory.

A badly balanced pulley, running at a high speed, will impart an unsteady motion to the belt running on it. The machine so driven makes bad work.

When a belt gets saturated with waste oil, an application of ground chalk will soon absorb the oil and make the belt workable.

Where possible, all belts should be run with the driving or tight side under the pulleys. The sag of the upper or slack side helps the belt to hug the pulley to the extent of 20 per cent. gain in driving power, as compared with a belt running with the tight side uppermost.

Belts running over pulleys of small diameter at high speeds ought to be as thin and as wide as possible. Orange-tan leather of uniform thickness answers remarkably well.

HIGH-SPEED BELTS.—A belt made from selected orange-tan leather, not too thick, softened, and made flexible, is the toughest and best leather belt for this class of drive. This belt will transmit great power when running at a belt speed of six to nine thousand feet per minute. The pulleys used for such drives must be strong and equally balanced, carefully turned to template, having a convexity no higher than one-sixteenth of an inch. Such pulleys must be hung perfectly true to each other upon the driving and driven shafts.

Thin belts, as wide as possible, give by far the best results working vertically. A thick vertical belt will not hug the pulleys.

In the use of vertical pulleys and guide pulleys, these pulleys ought to be twice the width of the belt, having no flange.

For machinery requiring the continuous shifting of the belt, single orange-tan leather is too thin, but double is highly recommended.

Leather link belting cut from the butt and made concave to suit the convexity of the pulleys will transmit from 25 to 30 per cent. more power than a flat belt.

Orange-tan leather rope, 1 in. square, running at 1,000 ft. per minute, on pulleys not less than 4 ft. in diameter, will transmit 10 horse-power.

In lacing hair belts the laces should run in parallel lines, each row laced separately, and no stitches placed across between the rows.

* Abstract from 'Guide to Belt Driving.'

A circular saw belt ought not to be narrower than one-fourth of the diameter of the saw. The spindle pulley should be as great in diameter as the width of the belt.

The following show tensile breaking stresses of leather belting :—

British Oak-tanned	.	.	.	4500–5000 lbs. per sq. in.
British Orange-tanned	.	.	.	6000–6500 „ „

According to *J. E. Rhoades and Sons*, the strongest part of belt leather is about one-third the way through from the flesh or rough side ; it is therefore desirable to run the grain or smooth side on the pulley so that the strongest part of the belt may be subject to the least wear. The flesh side is not as liable to crack as the grain side when the belt is old, hence it is better to crimp the grain than to stretch it. Experiments at Cornell University (U.S.A.) have established the fact that under reasonable shop tension the flesh side will transmit but 35 per cent. to 80 per cent. as much power as the grain side, with an average of 50 per cent. to 60 per cent., depending on the belt, the tension, etc.

A report issued by the Leather Belting Exchange Foundation, at Cornell University, on experiments to determine the relative power-transmitting capacity of belts on vertical, angular, and horizontal drives, gave the following conclusions :—

1. A vertical belt transmitted about 12 per cent. less power under average conditions than a horizontal belt, at 7 ft. 6 ins. centre distance. The percentage difference varies somewhat with the centre distance.

2. A given increase in tension increases the capacity of a vertical belt more than it does that of a horizontal belt, and *vice versa*. Therefore a vertical belt is more sensitive to tension, and ought to be retightened a little oftener to maintain an equally uniform transmitting capacity.

3. At the higher tensions, vertical, angle, and horizontal drives perform more nearly alike, while at low tensions they are widely different in transmitting capacity.

4. The power-transmitting capacities of four drives with the tight side below fall in the following order : First, horizontal belt ; second, 45° belt ; third, 67½° belt ; and fourth, vertical belt. There is practically no difference between the horizontal and 45° drives, or drives in between these two, except at low tension, when the horizontal is better.

5. Comparing the effect of using the tight side above and below with 45° and 67½° belts, it was found that when the tight side was below, leather belts gave about 12 per cent. more power on the 45° drive and about 6 per cent. more power on the 67½° drive, under average operating conditions.

Opinion differs somewhat as to which side of the belt should be run next to the pulley face —the grain or the flesh side,—but the balance appears to be in favour of the grain side. In the case of a good belt the grain side should transmit nearly twice the power conveyed by the flesh side. One disadvantage of using the flesh side next to the pulley is that whenever slip begins, the strength of the belt gets ground away by the quicker-running pulley acting like a grindstone. By running the grain side next to the pulley face, the essential sinews and muscles on the flesh side are preserved, while the less important and harder grain side takes the wear and tear caused by belt slip. (*Liverpool Journal of Commerce.*)

Belt Pulleys.

These should be at least an inch wider than the belt, and the rim should be convex to keep the belt in the centre ; about $\frac{1}{16}$ in. to $\frac{5}{32}$ in. of convexity is usually allowed in pulleys up to 12 ins. wide and over. The ratio of the diameters of two pulleys which work together should not exceed 6 to 1. The distance apart should, if possible, be such that the arc of contact on the smaller pulley is not less than 165°. If the arc of contact is less the width of the belt should be increased (see page 858). The diameter of pulleys is seldom less than 50 times the thickness of the belt in the case of ordinary belts, or 30 times the thickness of link belts ; that is, if any reasonable amount of power is being transmitted.

The slip in the case of a wood pulley with a single-ply oak-tanned leather belt is less than with one of cast-iron, if the belt tension is low.

Wood Pulleys.

In many respects wood pulleys possess considerable advantages as compared with pulleys made from cast iron and steel.

A wood pulley is some 60 per cent. lighter than a corresponding cast-iron pulley, while a comparison of the weights of wood and steel pulleys shows an advantage of some 30 per cent. in favour of the former. The light wood pulley is easily handled, and erection is considerably simplified, while the fact that a saving in power is effected must not be overlooked. These pulleys are particularly suitable for reversing drives where it is essential that the inertia of rotating parts should be reduced to a minimum.

Results of tests made in the United States with wood pulleys in regard to rim speed show that a wood pulley could be run up to a speed of 28,889 ft. per minute without destruction.

BELFAST—2 Linenhall Street, W.	Central 4292	Tullibody, Belfast.

With the same belt tension 33⅓ per cent. more power can be transmitted with a wood pulley than with either cast iron or steel, so that to transmit the same horse-power the belt on a wood pulley need not be so tight, and in consequence the strain on the bearings is relieved.

A belt obtains a better grip on a wood pulley than on an iron or steel pulley, so that there is much less liability of belt slip, and in consequence the life of the belt is enhanced.

Wood pulleys have been used to transmit up to 1,400 h.p.

A Simple Method of Crowning a Flat Pulley.

A belt-driven generator in a plant was originally fitted with a flat-faced pulley, and the belt would frequently run over to one side when an increase of load was thrown on the generator.

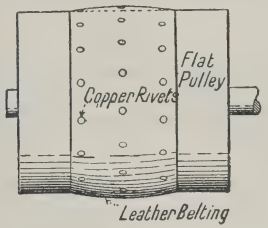

FIG. 4.

To overcome this, a crown was made on the pulley with leather lagging as shown by fig. 4. A piece of single-ply leather belting, 8 ins. wide, was procured and shaved down thin on the edges, and punched for three rows of ½-in. rivets. The leather was then fitted around the centre of the pulley, and the rivet holes were marked and drilled in the rim. The pulley was then warmed with a gasoline torch and a coat of belt cement applied and the leather pressed on smoothly, care being taken to draw it straight and to fit the ends together evenly. The rivets were then put in and headed up and the cement allowed to set twenty-four hours. This machine has run over four years since the job was done, and the driving belt has run perfectly under all conditions. (*Power.*)

Leather covers to pulleys are said to be conducive to excessive wear.

Belt Driving with Quarter or Right Angle Twist.

(1)

Fig. 5 shows the arrangement of pulleys for this purpose. In this case the centre of the bottom pulley should be in a dead line with the left-hand circumference of the top pulley, and the left-hand circumference of the bottom pulley should be in a dead line with the centre of the

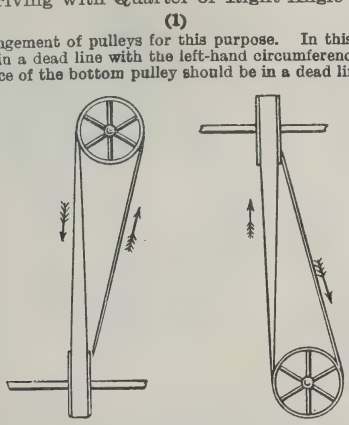

FIG. 5.

top. This is the correct position, but in actual practice the position of both pulleys has to be sometimes slightly altered to suit the running of the belt; this is a very simple matter, as it only means moving the pulley along the shaft one way or the other until it is seen that the belt

is in contact with the face of the pulley. No 'guide' pulleys are necessary. The pulleys should preferably be slightly crowned, *i.e.* a little larger in diameter at the middle than at the edges.

In practice, the centre plane of the lower pulley should be to the left of the edge of the upper pulley by an amount equal to half of the belt thickness.

With thick belts this point is sometimes of importance. No shifting of pulleys should usually be required if the drive is correctly set out.

With horizontal drives at long centres and pulleys with small crowning, a little adjustment is sometimes called for to compensate for dropping of belt due to its weight or perhaps due to the difficulty of getting a true horizontal line when 'setting out.' (*Geo. T. Pardoe.*)

(2)

The position for the machine pulley, with respect to the pulley on the shaft, depends on the relative direction of rotation of the pulleys. In any event the machine pulley must be in such a position with respect to the overhead pulley that when a plumb line is hung over the falling side of the overhead pulley at the middle of its face, the line must touch the rising side of the machine pulley at the middle of its face.

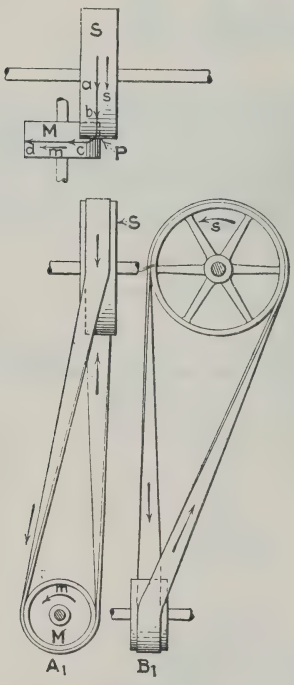

FIG. 6.

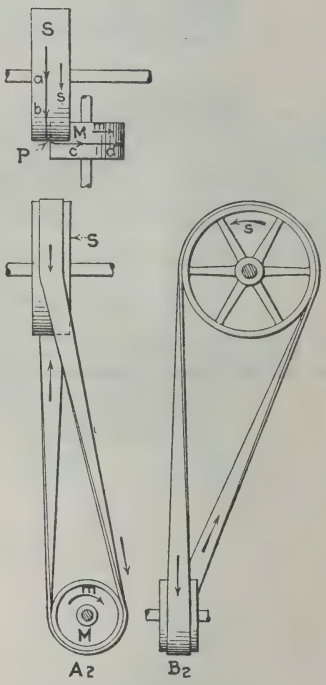

FIG. 7.

If S, fig. 6, is the overhead pulley whose direction of rotation is indicated by the arrow *s*, and it is desired to drive the machine pulley M in the direction indicated by the arrow *m*, then the middle of the face of the rising side of pulley M must be vertically under the middle of the face of the falling side of pulley S, that is, a plumb line hung over S at P, fig. 6 or fig. 7, should touch the rising side of pulley M at the middle of its face. It should be noted that where *s* and

m indicate the directions of rotation, whether in fig. 6 or fig. 7, the belt must pass over the top of the overhead pulley and thence to the far side of the machine pulley as indicated, in each plan, by the arrows *abcd*.

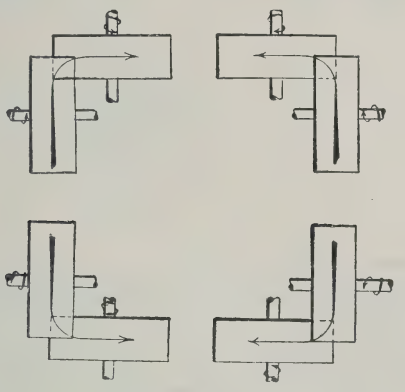

FIG. 8.

Mr. E. Bunzel points out that in laying out the drive, all that has to be seen to is that when looking down on the top of the two pulleys, the arrow of direction of the upper pulley follows the arrow of direction of the lower pulley. Fig. 8 shows the application of this rule for all four cases.

(*Power.*)

Link belts are not generally used for this kind of drive, but flat belts are made with a special curve to suit the drive in question; the curve of the belt varies according to the diameter of the pulleys, one to each other, and also to the length of the centres.

Putting on Heavy Belts.

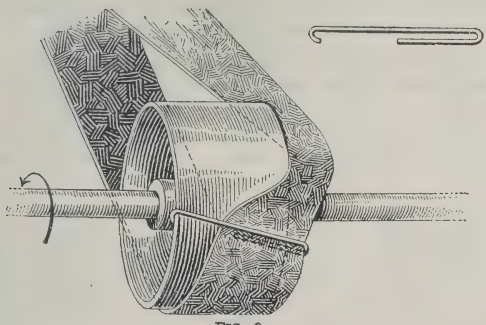

FIG. 9.

Fig. 9 shows a simple device for putting on heavy belts when it is necessary to shut down in order to do so, and where a rope is usually employed for the purpose.

Take a piece of $\frac{1}{2}$- or $\frac{5}{16}$-in. round iron and bend it, as shown in the small sketch. Hook the short end over the edge of the rim of the pulley and the long end under the belt as indicated. Start the engine slowly, and when the belt is on it is not necessary to stop, because the short end of the hook will straighten out and disengage itself. It is a good plan to use a rod of as light weight as will answer the purpose, since it will straighten out and free itself with less stress on the belt; the iron hook then falls to the floor. (*Power.*)

THE LINCONA ENDLESS BAND AND TENSION PULLEY DRIVE.

(James Dawson & Son., Ltd., Boultham Works, Lincoln.)

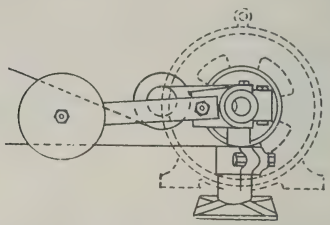

FIG. 10.

The degree of success obtained with the 'gravity idler' or 'jockey pulley' system of belt driving (fig. 10) has been governed by the difficulty of finding a fastener or joint which would stand up to the stresses produced by the severe bending resulting from the action of the idler pulley.

A further cause of failure has been the heavy stresses set up in the belt by the bending action round the small pulley usually found on such drives. The reverse bending, the high belt speed, and the short centres, all militate against the satisfactory operation of the ordinary type of belting. The 'Lincona Jointless Band' has been specially designed to meet the conditions, and is found to satisfactorily answer the required purpose. The joint is entirely eliminated, the basis of the belt being a very high tensile endless cotton band, which is impregnated with pure Balata gum, and folded, with the result that a very thin and strong belt has been produced, so that the bending stresses are reduced to a minimum, and frictional heat (which is rapidly destructive) is eliminated.

The advantages of a tension pulley drive are :—

1. A speed ratio of as much as 10 to 1 with a single drive.
2. The elimination of belt slip.
3. Saving in space, and, as a consequence of the shortness of the belt, the diminution of the collection of oil and dirt, and the avoidance of the inevitable 'taking up' for stretch.
4. A drive which is definitely over 98 per cent. efficient.
5. The efficient operation of vertical drives.
6. *A drive with all advantages of toothed gears and, in addition, the flexibility and 'safety-valve' qualities of a belt drive.*
7. The use of belt speeds up to 8,000 ft. per minute.
8. Much reduced belt tension, with the consequent drop in bearing pressure.

The belts are made to transmit powers as shown by the following table :—

'LINCONA' JOINTLESS DRIVING BANDS.

Steel Belting.

Steel belts have been recently introduced for the purpose of transmitting power, and are in somewhat extensive use on the Continent. These belts are from $\frac{2}{10}$ to $\frac{9}{10}$ mm. thick, and from 22 mm. to 200 mm. wide, as required. The steel for such belts is of a very high temper and is manufactured specially for this purpose. The difficulty of jointing the belt is one of the great objections. At present the joint is generally made by the makers, and is usually effected

by soldering the ends to a keep plate on both sides of the band, and made doubly secure by screws. The length of the belt is obtained by stretching a special tape to a predetermined tension across the pulley, and both ends of the tape are cut at the overlap.

These steel bands run quite well on the bare pulley, but there is a tendency to polish the same, and it is therefore desirable to cover the pulley with a very thin cork covering, which is glued on to canvas which in turn is cemented to the pulley. With this arrangement there appears to be little or no slip whatever. This is proved in practice by the fact that the cork covering does not wear away.

With such a belt, 32 mm. wide by 0·3 mm. thick, and cork-faced pulley, Prof. Kammerer, of the Charlottenburg University, transmitted 26·3 h.p. at a speed of 15·7 metres per second. Both pulleys were 1,250 mm. diameter, and the slip was equal to 0·91 per cent.

ROPE DRIVING.

Material.

As a material for driving ropes hemp has been superseded by cotton; even though a good cotton rope costs roughly three times the price of a Manila rope its greater suitability has resulted in the almost complete disuse of Manila in the British Isles.

In the U.S.A. at the present time there are only one or two rolling-mills which employ Manila ropes, the remainder having gone over to the use of cotton, mainly of the three-strand variety.

Construction.

The objection raised to four- and seven-strand ropes that they must be subjected to unequal rates of stressing is not admitted by all makers. Both three- and four-strand ropes are used for the transmission of power. The three-strand rope is rather more pliable than the four-strand and is rather stronger. On the other hand the four-strand rope has, according to Messrs. Thomas Hart, Ltd., a lower rate of stretch and may have a larger contact surface with the pulley grooves. It is admitted that it is a little more difficult to splice, and that a three-strand rope well spliced is better than a four-strand rope badly spliced. There is, however, an increasing tendency to order endless ropes so that the problem of inexpert splicing is removed.

Pulleys.

Rope driving pulleys are usually made of cast iron. The metal should be of a good blend, which leaves a hard, bright finished surface after machining.

Grooves.

Both straight-sided and curved grooves are in use.

The best angle to employ between the faces varies with conditions. Some makers recommend 40° and some 45° for ropes over 1 in. in diameter, and 30° for smaller sizes. Sharper angles are employed in specal instances.

The grooves of a driving pulley should be polished, and the pulley as a whole should be accurately balanced. Pulley grooves are generally cored in the casting, but are sometimes milled from the solid for small diameters.

The old practice of leaving rope grooves rough 'to help the grip' is fortunately discredited. Groove surfaces left unpolished in the machine shop have to be finished at the cost of the rope, which becomes worn.

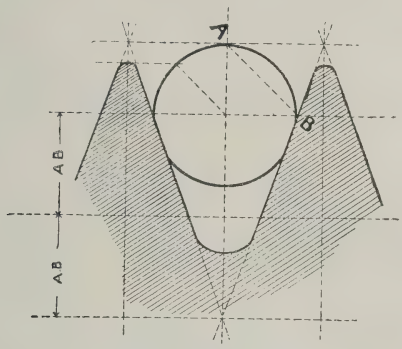

FIG. 11.—Flangeless groove with sides at 40°.

The method of setting out Hart's improved rope groove is shown by figs. 12 and 13. One great advantage of this groove is that it is made so deep as to prevent the rope ever reaching the bottom, a very important point.

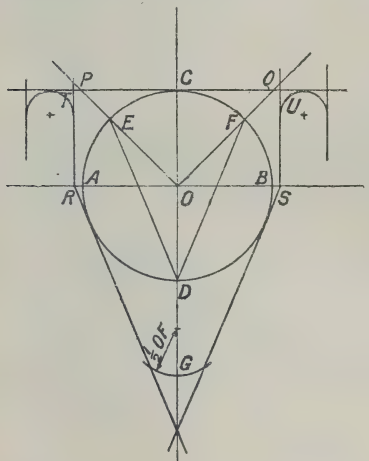

FIG. 12.

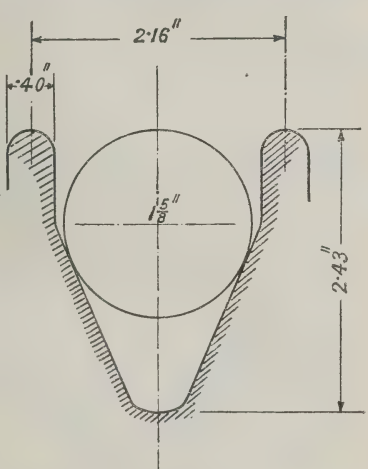

FIG. 13.

Section of Groove for Cotton Driving Ropes. (*Hart.*)

CONSTRUCTION FOR A 45° ROPE GROOVE.

With centre O and radius OA, draw a circle equal in diameter to the rope required.

Draw horizontal and vertical diameters AOB and COD.

With A, B, and C as centres, and radius OA, draw arcs to intersect at P and Q.

Join P and Q to centre O, cutting circle at E and F.

Join DE and DF, and parallel to these two lines draw tangents to the circle cutting AB produced at R and S.

Through R and S draw RT and SU parallel to COD, cutting PCQ, produced in T and U.

Make DG = DO and draw arc through G with radius = $\frac{1}{2}$ OA.

Thickness of mid-feathers = $\frac{1}{2}$ OA.

Round off all corners of the groove TRGSU.

SPEED OF PULLEYS.

The limiting peripheral speed for solid c.i. pulleys is 6,000 f.p.m., and 5,3000 f.p.m. for split pulleys. Built-up pulleys with wrot arms, steel spokes, and c.i. hubs have been employed up to 8,750 f.p.m. Experiments in U.S.A. with wooden pulleys have gone up to a peripheral speed of nearly 29,000 f.p.m. without failure.

Porosity of rim at root of arms, cracked bosses, and transverse cracks at smallest sections of the arms in c.i. pulleys are the great dangers which have to be avoided by careful design and regional cooling-off in foundry.

Systems of Rope Driving.

There are two systems of rope driving—the 'multiple rope' system and the 'continuous rope' system. These are sometimes, and without real justification, called the 'English' and 'American' systems respectively. The former is the most commonly used because, consisting

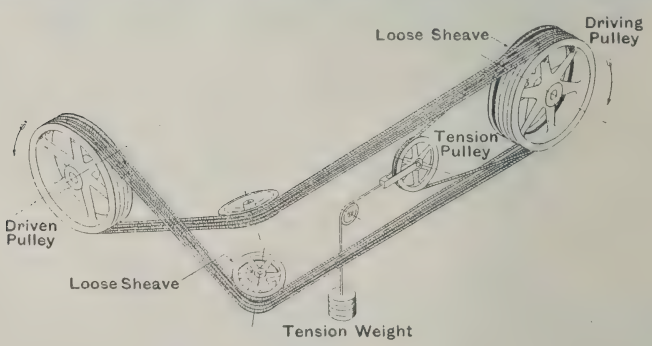

FIG. 14.

of a number of independent endless ropes running side by side, it has a great margin of reliability, which constitutes the unique advantage of rope driving. A crossed right-angle drive on the continuous system is shown diagrammatically by fig. 14.

By a reduction in margin of reliability the continuous drive can be usefully employed in some situations where a multiple drive would be expensive, inefficient, or inconvenient. Such cases are :

(1) Very short centre distances with large loads.
(2) Vertical drives.
(3) Limited widths with large loads.
(4) A few special angular drives.

A rope drive can be successfully arranged, by the aid of guide pulleys if necessary, for any possible relative position of the driving and driven shafts. This is the second great advantage of rope driving.

Design of Rope Drives.

The most important item in the design of a rope drive is to determine the correct ratio between pulley and rope diameters. The smallest pulley on the drive, *whether driving pulley or idler*, is the one to which this ratio applies. The old ' 30 times ' rule is obsolete, because the dimensional and speed limits have been widely extended during the past twenty years. Many rope drives are now running with highly satisfactory results, with a ratio of less than 10 in 1 between smallest pulley diameter and rope diameter.

Experimental work is still being carried out by the leading rope drive firms. The following is a table of rope pulley diameters extracted from a chart published by *Messrs. William Kenyon & Sons, Ltd.* This table is applicable to general heavy power conditions.

Minimum advisable Pulley Diameters in Inches.

Rope Sizes :	¾ In.	⅞ In.	1 In.	1⅛ In.	1¼ In.	1⅜ In.	1½ In.	1⅝ In.	1¾ In.	1⅞ In.	2 Ins.
Rope Speeds :	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins.	Ins
1,000	10	12½	15	18½	20	24	28	31	35	40	45

2,000	12½	15	18	21½	24	28	31	35½	41	44½	50
2,500	13½	16½	19½	23	26	30	34	38½	44	48	53½
3,000	15	18	21	25	28½	32½	37	41½	47	51½	57
3,500	16½	19½	23	27	31	35	40	44	50	55	61
4,000	18½	21	25	29	33½	38	43	47½	53½	59	65
4,500	—	23	27	31	36	41	45½	51	57	63	69
5,000	—	25	29	33½	38½	44	49½	54½	60½	67	74
5,500	—	27½	31	35½	41	47	52	58	65	71½	79
6,000	—	30	33	38	44	50	55½	62½	69½	76	84
6,500	—	—	35	40½	47	54	59	67	74	82	90
7,000	—	—	37	43	50	58	63	71½	79	88	96

For high-speed light drives, such as from electric motors running at speeds above 700 r.p.m., it is best to consult a leading firm, as the fullest possibilities are not yet recognised or even definitely tabulated.

Wherever circumstances permit a margin above the lowest possible ratio of pulley to rope diameter should be allowed, as this will result in a direct increase of rope life. In special instances it is permissible to go below the minimum ratio if a shorter rope life is economically justified.

Ropes ½ in. diameter have given over four years' life running on 6 in. and smaller pulleys at speeds of up to 5,000 f.p.m.

Transmissible Power of Ropes.

The power transmissible by a cotton rope depends upon—

(*a*) Groove angle ;
(*b*) Coefficient of friction between rope and metal;
(*c*) Running back tension on drive ;
(*d*) Ratio of pulley diameter to rope diameter;
(*e*) Ratio between pulley diameters.

Obviously some of these factors are functions of several other terms, and any generalisation or table of figures must be handled with caution.

The following table of powers, however, has been found to answer well in general practice.

TABLE OF POWERS FOR COTTON ROPES.

(Messrs. Wm. Kenyon & Sons, Ltd., Dukinfield, near Manchester.)

7,000	12·6	17·5	22·7	28·8	35·4	42·8	52·0	60·3	70	80·5	91·4

At a rough generalisation these figures may be accepted under the following conditions:

(1) Pulley grooves not exceeding 45° in angle and straight sided.
(2) Minimum centre distance approximately equal to twice the mean pulley diameter.
(3) Inclination to horizontal not exceeding 30°.

For worn or wide angle grooves, additional ropes are necessary.

The permissible ratio of tight side to slack side tension for different groove angles are given below:

Groove Angle.	Groove Coefficient of Friction. μ_g.	Maximum Advisable Value of $\frac{T_1}{T_2}$.
30°	0·36	3·1
35°	0·298	2·5
40°	0·27	2·3
45°	0·24	2·125

Taking the coefficient of friction of lubricated cotton rope on polished cast iron as 0·0926, any value can be determined from the expressions:

$$\frac{T_1}{T_2} = e^{a\mu_g} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where μ_g = groove coefficient;

a = arc of contact of ropes on smallest pulley, in radians;

e = base of Naperian logs.

And

$$\mu_1 = \mu \operatorname{cosec} \frac{\theta}{2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where

μ = real coefficient of friction for flat surfaces.

θ = groove angle in degrees.

Centre distance is not limited except where the slack side of a drive is uppermost. Then the drive should be no longer than will permit a maximum sag of 10 per cent. before the two sides of the drive rub.

Rolling-mill drives have been installed with the pulley rims almost touching. If there is no limit to width, the multiple system may be used. If width is limited, the continuous system with a suitable tension weight will generally overcome the difficulty.

Rope Driving Speed.

At one time an arbitrary critical speed was fixed for rope driving at 4,800 f.p.m. This was determined by fixing a maximum permissible tension for each rope and subtracting the centrifugal

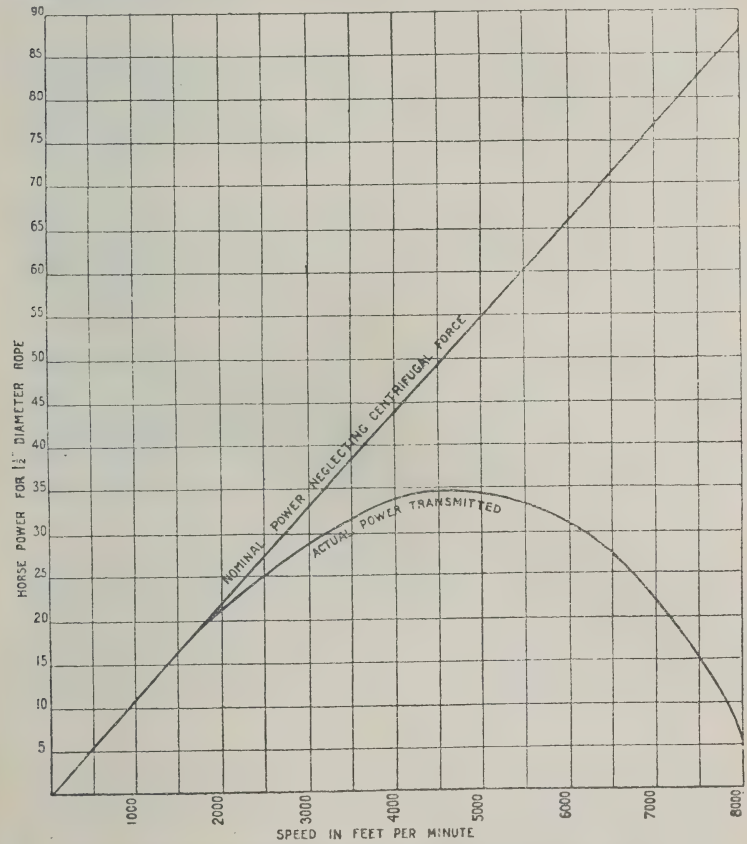

FIG. 15.—Diagram showing the effect of Centrifugal Force at different speeds of rope.

tension from this, the remainder being assumed to be the determining factor in power capacity. The result of these assumptions was a curve of horse-power capacity reading a maximum at 4,800 f.p.m. and then falling back to zero at about 8,300 f.p.m. as shown in fig. 15.

The total direct tension on a driving rope is, however, of small importance. The resistance to slip in the grooves is what determines maximum capacity, since a rope will slip along before the tension approaches the ultimate strength of the rope.

Furthermore, bending stresses are more important than direct stresses from the point of view of wear.

In practice the maximum direct stress in a driving rope at 4,500 f.p.m. does not exceed $\frac{1}{10}$th of its ultimate strength, and may, therefore, be increased appreciably without detriment, *provided the slipping point is not reached.*

Increase of speed actually raises the slipping point, because, if T_c is centrifugal tension; then the total running tension on the tight and slack sides respectively become $T_1 + T_c$ and $T_2 + T_c$, and it is obvious that

$$\frac{T_1}{T_2} > \frac{T_1 + T_c}{T_2 + T_c}$$

That is to say, for constant values of $e^{\alpha\mu}$ and T_2, as T_c increases, T_1 may be increased also. The power transmitted is a direct function of $(T_1 - T_2)$ so that power capacity actually increases with speed instead of decreasing. Allowance has to be made for bending stresses and increased rate of wear, however, so that the curve of capacity is actually below the straight line shown on fig. 15, but it continues to have a positive inclination up to a speed of 10,000 f.p.m. This explains why 2 in. diameter cotton ropes are actually transmitting 125–150 h.p. each at 8,750 f.p.m. on a Belgian rolling mill drive, with satisfactory results, when, according to the old theory, they ought not to be capable of transmitting power satisfactory at all.

Steadiness.

The use of cotton driving ropes for rolling mills in order to cushion heavy 'peak' loads is quite old; only recently, however, is the importance of resilience being appreciated in other directions. A book on 'The Driving of Spinning Frames,' published by Messrs. Wm. Kenyon & Sons, Ltd., gives a selection of tachograph records showing very strikingly how an irregular torque on a lineshaft can be damped out or considerably improved by the intervention of a rope drive.

Efficiency of Rope Driving.

Accurate and detailed data in respect of large drives is very scanty. Tests carried out by Prof. Bonte at Charlottenburg before 1914 on a drive of 200 h.p. capacity showed that rope efficiency increased with both speed and with loading. There is no simple law, however, and low loading it appears probable that efficiency will fall off beyond a speed of approximately 4,600 f.p.m.

For average rates of loading efficiencies of from 96 per cent. at 1,500 f.p.m. to 98·7 per cent. at 5,000 f.p.m. were obtained. This seems to indicate that the friction losses on ropes running under ordinary industrial conditions need not exceed 3 per cent.

Small drives usually have slightly lower efficiencies on account of the lower ratio of pulley to rope diameters, but at very high speeds efficiencies of 99 per cent. have been obtained.

Drives with Irregular Impulses or Loads.

When either the load or impulse is irregular, there are two main effects which must be provided against. The first is, if the ropes are fully loaded, or nearly so, for the general conditions of the drive, the irregular load or impulse has the effect of causing the ropes to slip, although under a load equal to the average load the drives might run perfectly well. In driving from single cylinder gas-engines (old type) as much as 50 per cent. extra ropes were sometimes found necessary. For a modern gas-engine 10 per cent. extra ropes are advisable.

The second is, that with either irregular impulses or loads, the ropes have a tendency to lash about, which, if not controlled, tends to excessive wear. The best thing to do is to regulate by flywheel effect and thus get rid of this action altogether. This, however, is not always possible. In that case the provision of a rope guard is advisable.

Rope Guards.

A design of the rope guard which has been used with great success is shown in fig. 16, and the method of installation in fig. 17.

To construct this, first determine the pitch, P, of the pulley grooves; let D = rope diameter, then thickness of blade $= P - \left(D + \frac{D}{8}\right)$.

The blades should be made of a good hard wood of even grain, without knots, with rounded edges, as shown on enlarged section. The ends are shaped to fit slots in cross-bars of frame where they are held in place by stretchers secured with coach-screws, thus facilitating replacement in case of breakage.

ROPE GUARD.

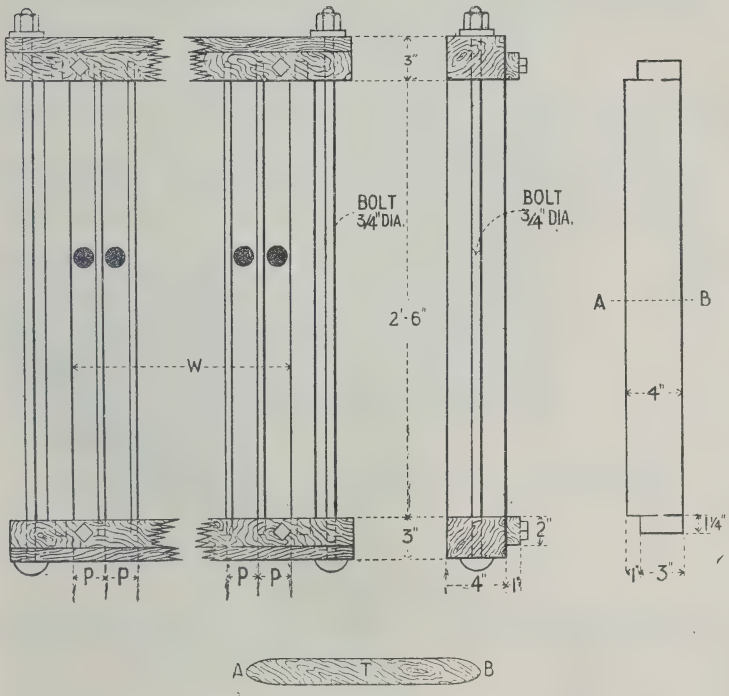

FIG. 16.

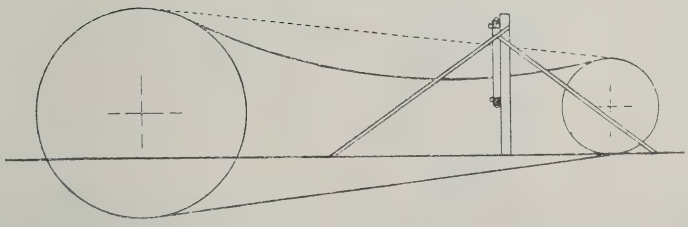

FIG. 17.

The method of applying this rope guard depends upon the relative positions of the two pulleys and direction of rotation. In oblique driving it is often attached to the roof or sides of a building, stayed by iron rods and tilted to meet the driving angle. These thin wooden blades are quite sufficient to stop the largest ropes from lashing; the action of lashing being accumulative, the blades steady each small impulse as it arises.

Long keyways are advantageous in fixing up angular drives, as they enable the pulley to be moved to the most desirable position in the circumstances.

Adaptability of Rope Drives.

In the case of a vertical half-cross drive, such as that shown in fig. 18, it is only necessary for success to ensure that the relations of the pulleys are such as to allow the slack to fall in a direct line, while the tight is deflected in the manner shown in the figure.

A right-angle drive is shown in fig. 19.

It will be seen that in this case the rope runs over four guide pulleys, so arranged in pairs of unequal size that the larger diameter leads to the smaller one, and *vice versa*. These guides run freely on studs which may be moved along the slotted sides of a rectangular bracket, thus serving as rope tighteners if required.

FIG. 18.

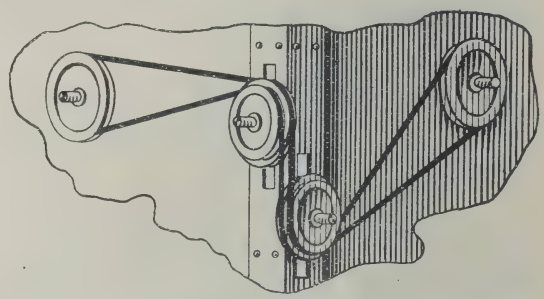

FIG. 19.

FAST AND LOOSE PULLEY.

Fig. 20 shows this combination in its most approved form. The working groove is set out at an angle of 30° on the lines previously described. A shallow intermediate groove provides for a gradual start and knock off, corresponding to the slip of a belt. The loose groove on the

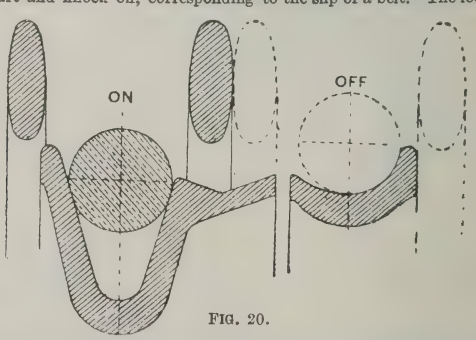

FIG. 20.

right is simply hollowed out to fit the rope, and is flanged on one side only. The rope shifter usually takes the curve of the pulleys, and is attached to a radius shaft and actuated by a small lever. A slight force on the slack side suffices to pass the ropes in or out of gear, and there is very little friction.

Notes on Rope Driving.

The following *Hints to users of ropes* are taken from Mr. Thomas Hart's book on 'Rope Driving':—

Take care that ropes do not get wet; water does them much harm.

Take care that ropes do not rub on anything in their flight, either when running at full speed or when starting and stopping the engine.

Take care that ropes do not slip; if they slip they are probably overloaded, or are too small for the grooves.

All ropes should be lubricated with a good anti-fraying and lubricating composition. Black-lead mixtures should not be used.

Instructions for Splicing Lambeth Cotton Driving Ropes (Four Strand).

(*Thomas Hart, Ltd., Blackburn.*)

Storing, Stretching, etc.

If it is necessary to store the ropes before fixing, they should be kept in a dry room, not on an earthen floor. When ready for fixing uncoil the ropes left-handed—the opposite to the way the hands of a clock move. Then stretch out with a pair of hand blocks, but do not allow the rope to revolve during this operation, or the 'turn' or 'twist' will be taken out of it. Everything depends upon the strength of shafting, etc., as to how tight the rope should be stretched, but under ordinary circumstances it is usual to have about four men pulling on a pair of hand blocks. Pass a string around the drive to get the exact running length of rope, and by tying two bands around the rope, mark off the exact running length whilst it is on the stretch, allowing ten feet (five feet each end) for the splice. For ropes 2 ins. diameter allow 12 feet of splice.

Splicing.

Unlay the five feet each end that has been allowed for splice, that is, as far back as the bands which mark the running length of rope; it is advisable to tie a string around the end of each of the loose strands to prevent the twist from coming out. The strands are now interlaced together, one from the right-hand side being next to one from the left-hand side, and so on, as shown in fig. 21. These strands should be pulled tight so that the bands butt together, and

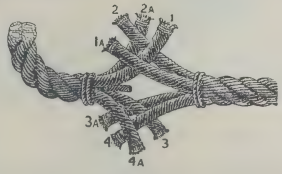

FIG. 21.

the loose strands on one side tied temporarily around the rope to keep the two ends of the rope in the position they now are.

Cut one of the bands, say the one on the right, and unlay strand No. 1A, at the same time laying in its place its fellow strand No. 1 from the opposite side of the rope. Do this for about four feet, and tie the two strands temporarily until all are ready for tucking in. The next strand to this, as will be seen in fig. 21, is numbered 2, but do not touch this now; take the next strand but one, numbered 3A, and unlay it, laying in its place strand No. 3, but only for about 1 ft. 6 ins.; tie these temporarily. It is very important in splicing four-strand ropes that two strands next to each other should not be laid up in the same direction.

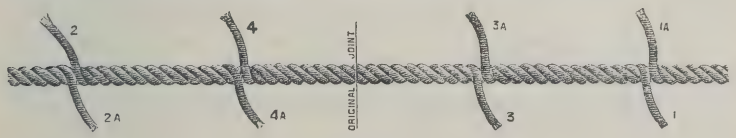

FIG. 22.

Next cut the other band, and proceed in the same manner with strands No. 2 and No. 4, but of course in the opposite direction. Care should be taken to keep the 'turn' or 'twist' in the strands, and they should be laid well and evenly down in their places. The splice should now be as fig. 22.

Begin now at joint No. 1 and 1A; untie the temporary fastening and shorten the strands to equal lengths of about 1 ft. 6 ins. An examination of the strands will show that the outside layer is composed of ten threads; for reference we will call these the friction bands; the internal portion of the strand we will call the tension strand. Take No. 1A and remove from it the ten friction bands and divide them into two lots of five, but do not cut them off. Now take strand No. 1 and unlay it two turns or laps, and whilst it is there remove from it the ten friction bands, divide them into two lots of five, but do not cut off. Now lay in again the tension strand only of No. 1 turn, and reduce it by leaving out about one-quarter, lay up the remaining three-quarters one turn, thus bringing it up to tension strand of No. 1A; tie the two with an overhand knot. At this knot the rope should be about its original diameter, and the joint should appear as shown in fig. 23.

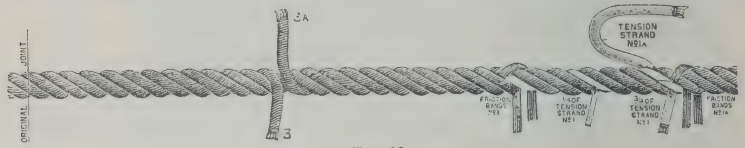

FIG. 23.

Take tension strand 1A and with the splicing pin work it under and over tension strand No. 1, as shown at fig. 24, passing it under and over spirally about five times; it will then have reached friction bands No. 1.

FIG. 24.

Now reduce it by cutting out a portion, and pass the remainder between the two lots of five friction bands, and lock by passing once or twice through the centre of the rope. This is clearly shown at fig. 25. Five friction bands are also locked through the rope as shown. This complete, turn to three-quarters of tension strand No. 1; this is locked exactly as tension strand No. 1A,

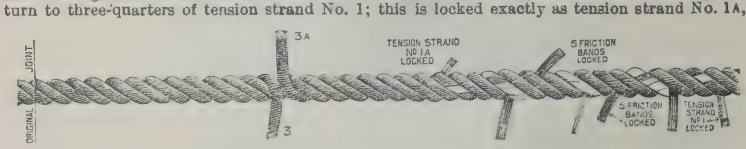

FIG. 25.

five of the friction bands are also locked as previously shown, and the splice should now be as fig. 25.

All loose ends are cut off and this portion is complete. Treat the two other joints in the same way and the splice is complete.

How to put a Rope on the Pulleys.

Put the rope on the small pulley, and as far around the large pulley as it will go; lash it there, but have the lashing so that the rope has freedom to slip through it. Then bar pulley slowly round by hand, or barring engine if there is one, and the rope will fall into its place. The groove of the small pulley and the face of the large pulley where the rope will touch in barring on should be well greased with tallow to prevent wedging. A piece of canvas may also be put on the rim of the large pulley to prevent it cutting the rope. (*Thomas Hart, Ltd.*)

Sizes of Pulleys and Drums.

The sizes of pulleys and drums should preferably be about ten times the circumference of the ropes to be used on the same, or, say, 1 foot in the diameter of the former for each pound of rope per fathom—*e.g.* a drum 3½ feet in diameter for a rope weighing 3½ lbs. per fathom.

V-Belting.

The capacity of a belt to transmit power depends upon the tension, the coefficient of friction, and the area of contact. By giving a belt the V-shape, the area of contact is greatly increased, for contact is along the sides. The area of contact also is increased by the wedge action of the belt in the groove, which forces the belt against the sides of the groove, and ensures that the entire surface of the belt passing over the pulley actually will be in contact with it. The V-belt gives maximum power transmission for a given width of pulley.

Whether a flat belt or a V-belt should be used depends largely upon the power to be transmitted and the speed at which the belt must be run. The V-belt will be found to operate satisfactorily at speeds as high as 3,500 feet a minute, while with flat belts on small pulleys, speeds up to 10,000 feet a minute are practicable. Single V-belts of $\frac{3}{4}$-in. width, running at 3,500 feet a minute on correctly designed pulleys, will transmit up to 3 h.p. If more power than this is to be transmitted, it will be found better practice to use twin belts, as shown at C, fig. 26, rather than to increase the size of the belts.

Pulley Grooves for V-Belts.

The pulley groove for a V-belt should be at least $\frac{3}{16}$ in. deeper than the belt thickness, to provide clearance, as indicated in fig. 26. A clearance of $\frac{1}{4}$ in. is better and usually will be found ample in any case. A V-belt must not bottom in the groove, as this would prevent the proper

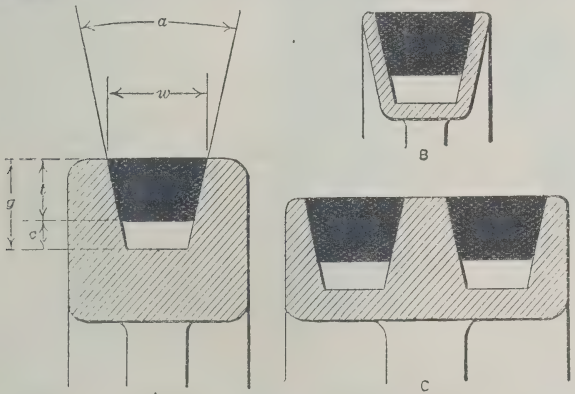

Fig. 26.

contact between the sides of the belt and the sides of the groove, and would seriously reduce the ability of the belt to transmit power. The width w of the pulley groove across the top of the V should be the same as the width of the belt, with a permissible tolerance of $\frac{1}{32}$ in. The sides of the groove, which form the contact surfaces, should be smooth, care being taken to avoid ridges, tool chatter marks, and other defects, as these cause rapid belt wear. The rim of the pulley should be as light as possible, as shown at B, except when a flywheel effect is desired, in which case the mass of metal in the rim should be increased, as shown at A.

Experiments have resulted in a recommended angle a of 38° for two-pulley drives. An included angle of 28° is recommended for the smaller pulleys of a three-pulley drive, due to the reduction of angular contact in this arrangement. The thickness t of a V-belt should be from 0·5 to 0·6 of the width w at the widest part of the V.

The 'Lincona' Balata 'V' Belt Rope.

(Patent.)

(*James Dawson & Son, Ltd., Boultham Works, Lincoln.*)

This driving rope, fig. 27, consists of a number of sections, each being built up of piles of cotton duck thoroughly impregnated with Balata gum (*Minusops Globosa*). The sections are held together with the Balata gum, and by a specially shaped rivet designed to prevent any creeping of the sections.

The belt rope is built up in such shape that the driving surfaces exactly fit the sides of the pulley grooves, fig. 28, and so provide a maximum of frictional surface in relation to the cubic measurements of the rope.

Advantages claimed for the 'Lincona' Balata 'V' belt rope are:—

1. It has a large frictional contact surface with the sides of the pulley groove, distributing the weight of the pull and protecting the internal fibres from side pressure, thereby ensuring long life.
2. The coefficient of friction is high, as no dressing or lubrication is necessary.
3. It can stand a heavy economical working tension on the pulling side. The breaking strain of a 'Lincona' Balata 'V' rope of 1 sq. in. section is 5,000 lbs.
4. As a result of the above it is capable of taking the heaviest loads at the highest speeds. A 'Lincona' Balata 'V' rope of 1 sq. in. section will transmit 60 b.h.p. at 4,000 ft. per minute, and give a satisfactory life and freedom from stretch.
5. Because of its high power transmission, a small number of ropes are required, therefore little power is absorbed in the transmission itself.
6. The joint is a simple splice, which any handy man can learn to make in a few minutes; thus the work of putting on the ropes can be done on the spot and at once.
7. No dressing and no attention needed once the ropes have been fitted.
8. No ill effects from damp or exposed conditions.

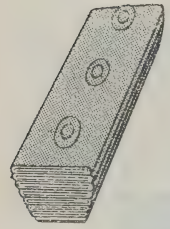

FIG. 27.

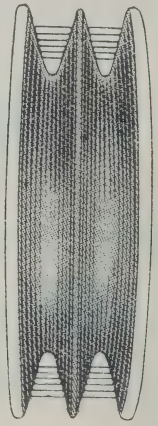

FIG. 28.

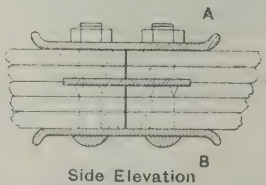

Side Elevation

Section through A.B.

FIG. 29.

This type of rope is being used extensively on steel rolling mill drives, main drives, pumps of all descriptions, fans, D.C. generators, and haulage gearing, and is giving improved service and life.

It can be satisfactorily fitted to grooves already in existence for interstranded cotton ropes, some slight alteration in design from the standard rope being necessary to effect a perfect fit in the groove. New installations should be fitted with pulleys having grooves of an angle of 28°.

When *Jointing*, the belt is drawn together by means of screw clamps, the several sections are cemented and riveted, the butted joints of each section being staggered in such a manner as to ensure the rivets being kept upright.

When fitting or taking up it is important that only the sections of the butted joints on one side are cut. The sections of the other half of the joint then act as a guide to correct cutting.

A fastener capable of holding together the butt ends of a Lincona belt rope has recently been devised; it forms a compact and strong joint which will stand up continuously to the heavy strains which it is required to bear. The arrangement, fig. 29, consists of three strong metal plates, A, B, and C, provided with spikes (shown dotted), the centre plate having these spikes on both sides. Bolts pass through the plates and bind the latter and the ends of the belt firmly together.

The following table represents length of life and freedom from bearing trouble rather than a high power figure; it will be found to be reliable in practice for speeds up to 6,000 ft. per minute.

'Lincona' Balata 'V' ropes have been tested up to 7,000 ft. per minute and found to transmit the power given in the table.

From the table it will be seen that the horse-power is increasingly transmitted up to 7,000 feet per minute rope-speed, with a falling off noticeable after 4,000 feet per minute due to centrifugal force.

In calculating the number of ropes required for a drive, it is important that allowance should be made if the arc of contact of the rope on the smaller pulley embraces less than 180° of the circumference.

TABLE SHOWING HORSE-POWER TRANSMITTED BY 'LINCONA' BALATA 'V' BELT ROPE.
(Cross-section area of belt = 1 sq. in. Speed in ft. per minute.)

Speed	1000	2000	2500	2600	2700	2800	2900	3000	3100	3200	3300	3400	3500	3600
H.P. .	12·5	24·7	30·6	31·5	32·7	33·7	34·9	35·9	37·0	37·9	39·0	40·0	40·9	41·8
Speed	3700	3800	3900	4000	4100	4200	4300	4400	4500	4600	4700	4800	4900	5000
H.P. .	42·8	43·7	44·5	45·0	46·3	47·0	48·0	48·7	49·4	50·2	50·8	51·4	52·3	52·5
Speed	5100	5200	5300	5400	5500	5600	5700	5800	5900	6000	6500	7000	7500	8000
H.P. .	53·2	54·1	54·5	55·0	55·7	56·0	56·3	57·0	57·2	57·4	58·8	59·2	58·5	57·0

For any other cross-section area, multiply horse-power by this area.

The following allowance should be made:—

Arc	180°	170°	150°	140°	130°	120°
Percentage of power transmitted .	100	97	95	90	85	80

It must be borne in mind that the arc of contact is lessened if the slack is on the bottom of the drive.

An allowance, depending on the tension that can be put on the ropes, must be made if the drive is vertical or at an acute angle.

DICKBALATA
ELEMENT DRIVING
ROPES

A super driving rope of exceptional flexibility and durability, built for maximum service and guaranteed to give it.

◆ ◆ ◆

Easy to splice

Has Long Life

Price List on application

6 Ropes 2″×2¼″ transmitting 700 BHP. 3 1½″ Ropes driving Dynamo.

Positive grip owing to the large surface contact of the 'V' section

GREENHEAD WORKS, GLASGOW.

PATENTEES & ORIGINAL MAKERS OF

BALATA BELTING

AND DICK BALATA ELEMENT DRIVING ROPE

The Dickbalata Element Driving Rope.

(R. & J. Dick, Ltd., Greenhead Works, Glasgow.)

This rope is constructed V shape, as shown by fig. 30. The binder or top portion is made like ordinary Dickbelt (p. 856), with Dickbalata blocks solutioned and riveted to it.

The rope is of very great strength, as can be seen from the horse-power table (page 884); it is claimed to give practically double the power of cotton ropes. It does not need a special expert to fit it; any engineer or belt fitter can make the splice without difficulty and in quick time; the splice is as strong as the main portion of rope.

Fig. 30.

The Dickbalata Rope has positive grip, no slip, runs in steamy or damp atmospheres without being affected, and without noise; no dressing is needed. Owing to its flexible construction, the rope can be used at short centres if necessary and over small pulleys.

The rope can be used for cross-driving.

WIRE ROPES.

Lang's-lay.

In the 'Lang's-lay' all the wires forming the strands, and the strands comprising the rope are laid in the same direction. These ropes have been used for from 3 to 6 years hauling some 3,500,000 tons of coal, at speeds varying from 5 to 15 miles per hour, over distances up to 220,000 miles.

Haulage Wire Ropes, Useful Sizes (Lang's-lay).

Approximate Diameter.	Circumference of Rope.	Number of Strands.	Number of Wires in Strands.	Number of Wires in Core	Gauge of Wires.	Lay of Strands.	Lay of Rope.
Ins.	Ins.				In.	Ins.	Ins.
$\frac{5}{8}$	2	6	6	1	·072	$2\frac{1}{4}$	6
1	3	6	6	1	·105	3	$7\frac{1}{2}$
$1\frac{1}{4}$	4	6	8	7	·116	$3\frac{3}{4}$	9
2	6·2	6	10	7	·146	$4\frac{3}{4}$	13

The Third Report of the Wire Ropes Research Committee of the Institution of Mechanical Engineers gives in the summary the following:

Twelve wires to a strand with a fibre core was the best construction when associated with Lang's-lay.

Ordinary lay was best for nineteen-wire strands, 12 on 6 on 1, except on the pulley of 850 wire diameters.

A soft core wire in a seven-wire strand proved to be undesirable for a rope of high-tensile wire which was used on a small pulley.

A Lang's-lay rope with strands of six 100- to 110-ton wires laid on a soft core wire was best on a large pulley of 500 wire diameters, but even on this pulley the soft core wire was a weakness in a 80- to 90-ton rope.

6 × 6 and 6 × 7 ropes compared favourably with 6 × 12 and 6 × 19 on the same pulley when its diameter equalled 500 diameters of the larger wire, or 18 circumferences of either rope.

'Trulay' ropes were superior to those made by the usual method of manufacture, particularly on small pulleys and in 6 × 7 construction.

The Lang's-lay ropes with 12 wires to the strand on a fibre core gave particularly good results on pulleys of 500 wire diameters and larger, and under these conditions the alleged deformation of this form of rope will not occur.

WIRE ROPE SPLICING.

FIG. 31.

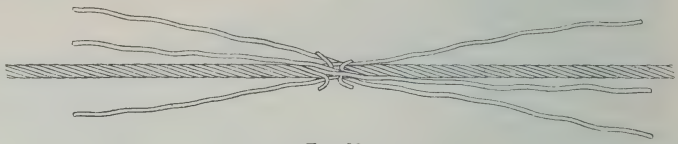

FIG. 32.

FIG. 33.

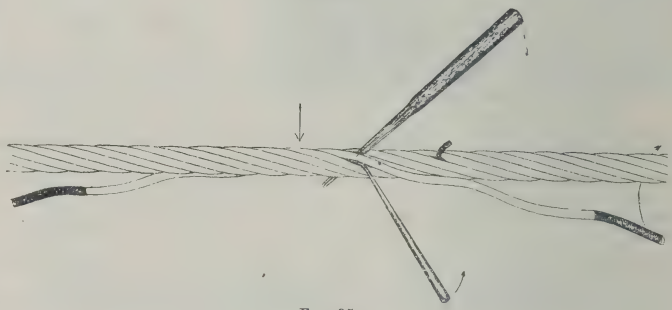

FIG. 35.

FIG. 36.

The tensile strength of a wire was reduced 18 per cent. by severe lateral pressure.

For 'Horse Power required for Haulage,' see p. 2598.

Wire Rope Splicing.

LONG SPLICE.

This splice is used for haulage and where endless ropes are required.

Mark off both ends the length required for splicing, which depends on the size of rope, say 48 ft., that is 24 ft. each end. Having marked each end, unlay three alternate strands from each end to within 6 ins. of mark, as shown in fig. 31, L, p. 886.

Cut off the three remaining strands with the core and bend back at mark, as shown in fig. 31, R.

Lock both ends together, close up, so that the long strands pass alternately right and left, as shown in fig. 32.

Grip the rope on one side of the lock with tongs, unlay one short strand and lay up in its place the corresponding long strand until within 4 ft. of the end. To facilitate operations, the short strand may now be cut 4 ft. from the cross, the two ends measuring 8 ft. Lay up the other two long strands, the crosses being 8 ft. apart; next repeat the operations with other side, cutting the ends at 4 ft. and the crosses being 8 ft. apart, as shown in fig. 33.

The next operation is to run the ends in and substitute the core. It is advisable to serve the ends, this gives the outer strands a firm grip on them and prevents loose wires protruding through interstices of the strands. Grip the rope with tongs where indicated by arrow, drive the spike through centre of rope three strands in advance of the strand to be run in, and with the aid of short spike pick the core out, as shown in fig. 34.

Run spike back towards the tongs, insert needle over the end in place of the spike, hook spoon under the end, and in same place as the needle, as shown in fig. 35.

Take two or three turns out of the strand and twist it round the rope as indicated by arrow, at the same time bring the handle of the needle and spoon together, as indicated. This forces the strand into centre of rope, and by twisting the needle round the lay the strand will enter the rope one side and force the core out on the other. Cut the core close up to the end of strand, and turn and run the opposite end in exactly the same way.

Run in the other five pairs of ends in exactly the same way as the first pair.

Care should be taken not to run the core too far back, otherwise flat places will occur.

This completes the splice, and if correctly executed there should be very little difference between the splice and any other portion of the rope.

With a Lang's-lay rope the ends of the strands are run into the right of each other, as shown in fig. 36, p. 886.

With the ordinary lay rope the ends of the strands are run into the left of each other.

Wire Rope Socketing.

Wire rope sockets should be made from carefully selected and tested steel of high strength, and be either drop forged or of well-annealed cast steel, depending upon the diameter of the rope to which the socket is attached.

When the work is done in the ordinary way the wires are bent back on each other and the basket of the socket filled in with metal, pins being used to lessen the quantity of metal required. In following this method it is important to have all the wires engaged, otherwise some of them creep back into the rope, thus preventing a perfect contact between the rope and the socket, consequently developing a weakness in the connection due to the disproportionate strain obtained on the strands.

When sockets are attached in the following manner, the full strength of the rope or the socket is obtained:—

The rope is first served securely with soft wire, fig. 37 (p. 888), and the strands opened, as shown for a distance equal to the length of the basket of the socket, and the hemp core cut out.

The wires are then separated in each strand, as shown, fig. 38, and well cleaned from all grease by means of petrol.

The wires are next dipped for a few minutes (not more than five) into a solution of equal parts of hydrochloric acid and water, then washed thoroughly in water, and dried. A stronger acid solution than that indicated should not be used.

The wires are then bound together by means of soft wire, as shown by fig. 39.

The socket being warmed, the wires are pushed through the basket of the socket till they are even with, or a little above, the top. The binding then being pulled off, the wires spring out.

Clay is put round the rope at the bottom of the socket to prevent metal running through, and then melted white metal is poured into the socket at A, fig. 40, until the socket is filled up, care being taken that the metal is not too hot to take the temper out of the wire.

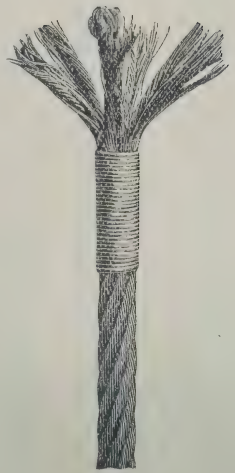

FIG. 37.

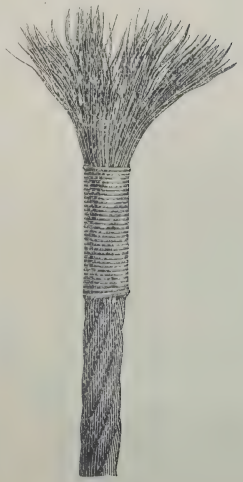

FIG. 38.

FIG. 39.

FIG. 40.

Ordinary virgin spelter is probably the best metal for socketing wire ropes, but this has to be used with caution, as it can be heated up too high unless the workman is very careful. As soon as it begins to char a pine stick (a match will do) should be used.

Another mixture that is recommended is 80 per cent. zinc and 20 per cent. tin; this has a low melting point and consequently is not apt to affect the wires. (*Brunlons, Musselburgh.*)

The Coal Mines Act of 1911 requires that the filling metal should not have a melting point above 750° F. Cast zinc is not good as a filler, as its melting point is high—786·9° F.—and it is liable to be heated considerably above this temperature.

Blackett's Wire-Rope Socket.

Fig. 41 represents a section of Blackett's wire-rope socket. The cap or socket, A, made of iron or steel, and fitted with a lining, B, of some soft metal, is placed round the rope-end, C, which is brought into proper position, and then forcibly driven outwards against the lining, B, within

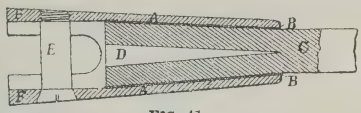

Fig. 41.

the socket, the wire ends being held asunder by a tapered plug, D, made of soft metal similar to the lining, B. A bolt, E, which serves to carry the load, or another socket, passes through a double eye. This arrangement forms a strong and compact job, and the process of socketing can be easily and rapidly performed.

Attaching ropes to joints or sockets by means of pins or rivets driven through the former is a detrimental, if not a dangerous, procedure.

Wire Rope Lubrication.

According to the operating temperatures that may be involved, and the possibility of the presence of an excess of water, the viscosity of a wire rope lubricant should be 1,000 seconds Saybolt at 210° F., or somewhat lower. In warm climates, or when the ropes are adjacent to ovens or furnaces, where there is danger of the lubricant becoming thinned down to such an extent that it will drip off, it is advisable to use a lubricant of about 1,000 seconds viscosity at the temperature prevalent under operating conditions.

On the other hand, in relatively cold districts, it is advisable to use a somewhat thinner lubricant selected in accordance with the range of the operating temperatures involved.

Wire rope lubricants should, in general, be straight mineral petroleum products, devoid of fillers or thickening mediums, i.e. whatever the viscosity, it should be an inherent property of the lubricant, not an artificial characteristic which cannot be depended upon. Greases or soap-thickened mineral oils are quite unsuited to wire lubrication.

Application of Wire Rope Lubricants.

As a general rule, wire rope lubricants must be applied in a heated condition.

The best method of treating wire ropes is to use a form of split box for the lubricant which can be parted to permit it to be placed around the rope, the hole through which the rope passes being on the parting line. The lubricating box may be made from wood or metal. The shape of the box is determined somewhat by the angle or position of the rope. For horizontal ropes, a V-shaped box or trough with holes at each end near the bottom is generally used. Conical shaped boxes or containers are used for vertical ropes, the rope passing through a hole at the small end of the cone. Boxes of the kind described can be readily built in the average plant, with suitable provision for rendering it sufficiently tight to prevent the lubricant from leaking out even when reduced in viscosity by heating. The slow passage of the rope through such a bath of heated compound will not only ensure thorough coating of the surface but also will cause the lubricant to penetrate to the inner strands. Further working of the rope over the sheaves before the lubricant has time to cool entirely will aid in bringing about maximum penetration.

It is good practice to apply lubrication at least every six months, and every three months under some conditions.

CLUTCHES.

Friction Clutches.

Fig. 42 is one of the simplest forms of friction clutch. Part A clutches with part B (which is keyed to the shaft) by advancing the latter so that the conical surfaces are pressed together: these surfaces are sometimes covered with leather or fibre in order to increase the frictional resistance. When the members are mounted on separate shafts, it is generally advisable to mount

the sliding member on the driven shafts so that it may be at rest when not engaged. Where oil is likely to lodge between the two parts, small escape holes should be drilled parallel to the shaft axis through one of the members. These holes also allow of the escape of any air which may be trapped between the faces.

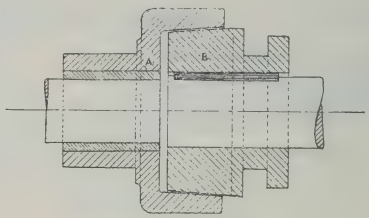

FIG. 42.

THE WESTON FRICTION COUPLING.

This device is probably more frequently used as a brake than as a clutch, but is equally suitable for both purposes. In the design shown in fig. 43, the muff A is keyed to the shaft S, but can be moved along the same by means of a fork which fits into the groove at the right-hand end. This muff A is provided with several feathers F around its inside surface (or the inside surface

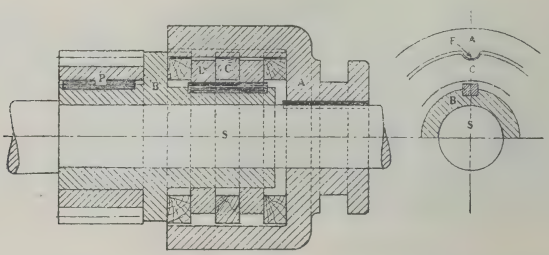

FIG. 43.

may be hexagonal), and into these are fitted the annular discs C. These discs are sometimes made of hard wood, but may be of iron. The member B, riding freely upon the shaft S, has a pinion P (or pulley) keyed to the outer end, and the metal rings D keyed to the sleeve. The rings D are free to move longitudinally along the sleeve, and are clear of the feathers F. Similarly the discs C are clear of the key in the sleeve B. On pressing A forward the axial force P is exerted on each of the rubbing faces and the frictional or turning effort increases with the number of rings.

The principle of the Benn and Hele-Shaw clutches is identical with the above.

THE HELE-SHAW INDUSTRIAL CLUTCH.

(*The British Hele-Shaw Patent Clutch Co., Ltd., Oldham.*)

In this form of clutch (fig. 44) all the plates have driving notches either on their outer or inner circumference. The plates with driving notches on their outer circumference are made from high-grade phosphor-bronze, the plates with inner driving notches being of high quality mild steel. The illustration shows a pulley type of clutch; in this case the drive may be transmitted either from the pulley D to the shaft by means of the core A, or *vice versa*. The plates are housed in an oil-tight casing, which revolves with the pulley. The cover B contains the springs L, which

maintain the pressure on the discs sufficient to transmit the drive, the end O is the mechanism for operating the clutch and also provides for adjustment when wear occurs.

The method of operation is simple. By means of a gun-metal strap ring with two pegs, which fits in the actuator H, the toggles, I, are moved. These move the presser J, which in turn moves the pins K, compressing the plates together.; this compression of the plates usually being sufficient to start the transmission. As the presser J moves over further, the springs L are compressed until sufficient pressure is put on the discs to ensure transmission without slip. When wear takes place the clutch is maintained in efficient condition by putting into the driving position whilst stopped, the pin M is removed and the ring N is screwed up one or more turns until the springs are again fully compressed.

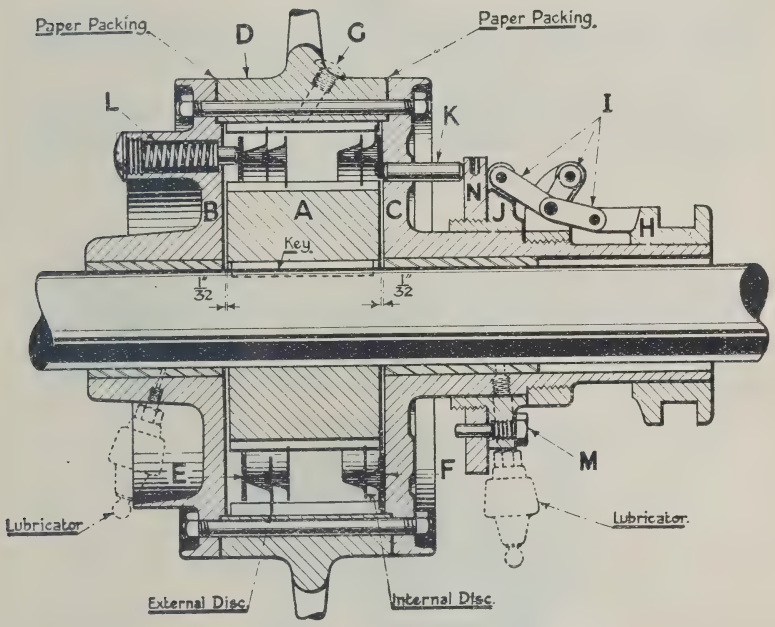

FIG. 44.

The ease with which a Hele-Shaw Clutch is operated is due in part to the mechanical advantage obtained from the toggles and from the slow compression of the discs. It should be noted that the discs, running in a bath of oil, engage without any jar, and that acceleration is gradual through out. The clutch is self-locking both in and out of gear, and that there is no thrust on the shaft when in gear or out of gear.

The Hele-Shaw Clutch can be arranged in various forms: pulley, coupling, gear clutch, a pair of clutches combined for a reversing motion or with an extended boss to take small gear or pulley.

In practice it is found that the V-grooved twin plates are approximately three times as powerful as the same number of flat plates under the same pressure, and hence for the same work require one-third the spring pressure or operating pressure to engage. The plates being well separated right up to the point of work, and their only touching at the side of the V-grooves, free circulation of oil and extreme rapid dissipation of wear are ensured, so that plates never burn the oil, and may be engaged indefinitely without causing undue heat, whilst their working condition remains constant, also long periods of slipping can be endured as part of their regular work.

The V-groove in the twin plates adds so greatly to their traverse strength that buckling and distortion are impossible. Even under the most unfavourable working conditions, such as through accidental loss of oil and extreme heat being set up, the V-grooved plates still retain their shape.

The latest development of the Hele-Shaw Clutch is a Safety Coupling. It is in appearance similar to a Hele-Shaw Clutch without the operating end. This consists of a coupling which is permanently in gear, but which is capable of transmitting power without slip up to a predetermined maximum. When the maximum power is exceeded, slip takes place, and shows the operator that an abnormal condition exists. Slipping may be maintained for more than five minutes without damaging the coupling. These couplings are usually applied between an electric motor and a worm-reduction gear.

The advantages of the Hele-Shaw Safety Coupling are these :—The power at which slip occurs is adjustable and is also more constant than other types, such as are used when a pin is sheared. The internal parts are fully protected, and when the load returns to normal the coupling picks up the load smoothly and then acts as a solid coupling until further overload develops.

The Hele-Shaw Clutch is ideal for use in exposed positions, such as out of doors, in coal-mines, etc., as the friction surfaces are fully protected, and, furthermore, since it is a clutch running in oil it is especially suited for use with chain drives, as the driving chain requires lubrication, which is detrimental to Ferodo type clutches. The applications are universal, such as :—electric winches for ships, machine tools, paper-making machinery, cable-making machinery, etc., etc.

The Benn Friction Clutch.

In this clutch (Type H), fig. 45, the friction plates move axially, practically bear against the entire faces of the drum, and are continuous. As a result of this construction the diameter, for a given power, is relatively small. As the movements of the plates are axial and not radial, they are unaffected by centrifugal force and the drum being relieved from bursting strains the clutch is suitable for high speeds. The lever stops H, as they approach, show at a glance the amount of wear and compensation, for this can be made by screwing in the plate M one or two notches. By screwing out the ring M and slacking back two set screws, the interior parts can be withdrawn without disturbing the shafts or parts keyed thereto.

The construction and action of the clutch is as follows :—

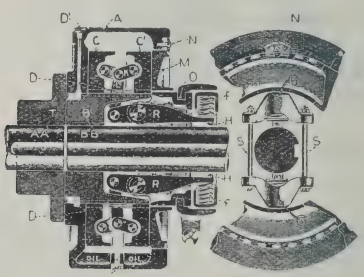

Fig. 45.

The boss T of drum A is keyed to the shaft AA, and the driving boss B to the shaft BB. On the driving boss B, the friction plates CC′ are free to slide on feathers DD. These plates CC are connected by toggles KK, which, in turn, are connected by radial links LL to the levers RR. The ends of these levers RR carry compression springs FF, having their outer ends seated in the yokes GG. These yokes are connected to each other by the bolts SS, thus forming an equalising member, which absolutely *ensures uniform pressure* between all friction surfaces throughout the clutch. The cover M, forming one end of the drum, is accurately adjustable, and is notched to receive the lock plate N. The lever stops HH are to enable the position of the toggles KK to be ascertained from outside the drum.

The figure shows the condition of the clutch when engaged, i.e., the plates bearing against M and A, the muff O in its inmost position, springs F in compression, the toggles KK in their most advantageous position (nearly straight), and the clutch locked by the radial link L being beyond the centre. On withdrawing the muff O the link L is pulled towards the right, the toggles KK are drawn towards the centre, and the plates C withdrawn from the drum faces.

The Johnson Friction Clutch.

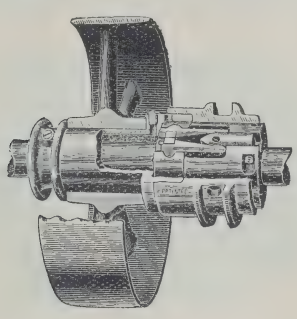

Fig. 46.—Clutch with Pulley Mounted on Hub.

This clutch, figs. 46, 47, consists of a body fastened to the shaft and carrying a split ring into which are inserted a pair of levers. A curved shaped wedge, which is made part of a sliding sleeve, forces the levers apart, expands the ring, bringing its outer surface into fractional contact with the inner surface of the friction cup, the hub of which is made to suit requirements. One screw which moves two taper blocks, set into the levers, adjusts the contact of the ring and cup to any degree.

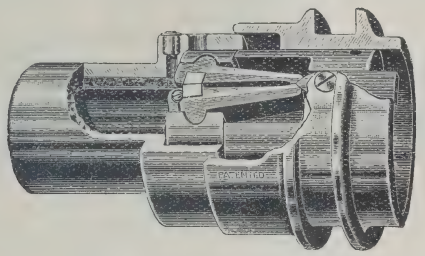

Fig. 47.—Section broken away, showing Clutch disengaged.

Patent Automatic Trip Centrifugal Clutch.

This clutch, fig. 48, has been designed for use with electric motors, driving any class of machinery, *to enable the motor to start without load and to automatically pick up the load* when a certain speed has been attained.

For three-phase and two-phase motors of the squirrel-cage type, as well as for all single-phase induction motors which possess a low-starting torque, a clutch of this description is most essential.

The clutch consists of a cast-iron body (B), keyed to motor shaft and provided with machined slides to receive the slippers (S), and with fulcrum pins (F) to carry the trip levers (L).

The slippers (S) are of cast iron, machined to suit the slides in body (B), and are shod with 'Perodo' friction surface linings and fitted with pins (P) to carry rollers (A).

The trip levers (L) are cam-shaped to bear against the rollers (A) and hold the slippers (S) away from the friction rim (R). They are held in position by the springs shown, the tension on which may be adjusted by means of the adjusting bolts (T).

The action of the clutch is as follows:—When the motor has reached a certain speed, the centrifugal force of the levers (L) overcomes the tension of the springs, causing the levers to open outwards, and thereby releasing the slippers (S), which move outwards against the friction rim (R) and automatically pick up the load.

When the current is cut off, the levers are gradually returned to their former position by means of the springs, and withdraw the slippers from contact with the friction rim.

The clutches are *designed to engage at 75 per cent. of normal speed*, but the springs are provided with adjusting bolts to allow the slippers to come into operation at any desired speed between 50 per cent. and 90 per cent. of normal speed.

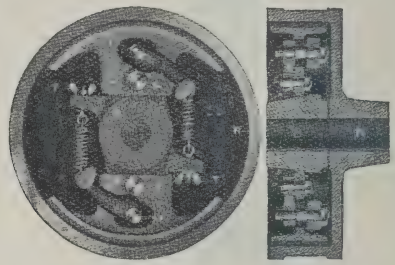

FIG. 48.

By this design of clutch *full advantage of the weight of the slippers* for the required frictional contact is secured, *thereby enabling the various parts to be as light as possible, and reducing the time of rubbing of the friction surfaces to a minimum.*

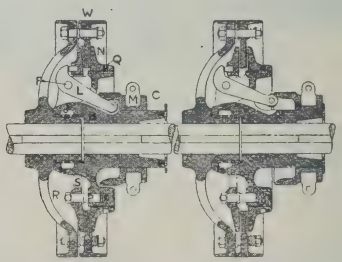
These clutches are made by Frank Wigglesworth & Co., Ltd., in sizes from 6 ins. to 30 ins. and capable of transmitting from 0·7 to 500 horse-power at a speed of 500 revolutions per minute. The power increases almost in proportion to the cube of the speed and fourth power of the size.

HIGH-SPEED DISC FRICTION CLUTCH.

The general design allows this type of clutch, fig. 49, to be run at very high speeds, and forms an ideal clutch in connection with electrical machines.

End pressure is not required to keep the clutch in or out of gear, and all projecting parts are shrouded.

Its construction is as follows:—



In Gear Position. Out of Gear Position.

FIG. 49.

The body (B) is a cast-iron circular disc, with boss bored and keywayed to suit shaft, and having lugs cast on the inside, forming fulcrums for levers (L).

Driving pins (*p*) are fitted into the body (B), which carry the inside annular friction ring (S).

The levers (L) are of steel, and having friction rollers fitted to one end to allow of easy movement of sliding collar over them.

The sliding collar is of cast iron, having extended circular flange, the inside being tapered in order to depress the ends of levers (L). It is complete with cast-iron clams (M), which receive the momentary pressure from operating lever for putting clutch in and out of gear. A spring grease lubricator is fitted to clams (M).

The shell (R) is a cast-iron circular bell-shaped disc, with boss bored and keywayed to suit shaft, and to its extreme diameter the annular disc is fixed.

The internal boss (J) is bushed with gun-metal, and forms a bearing for the extended boss of body (B), thereby ensuring perfect alignment of clutch. Grease lubricators are fitted to this bearing.

Its action is as follows:—

When the clutch is put into gear, the sliding collar (C) is moved (by means of operating lever) from the out-of-gear position (shown by dotted lines) to position shown on drawing, and depresses the ends of levers (L), their opposite ends pressing hard on the annular ring (S) gripping the annular disc against the friction face of adjusting ring (N).

When the clutch is put out of gear the springs shown force the rings clear of the ring (W), which also moves clear of the friction face on ring (N), as shown by out-of-gear position.

Adjustment is made by rotating the ring (N), and afterwards locked by locking screw (Q).

These clutches are made by Frank Wigglesworth & Co., Ltd., in sizes from 12 ins. to 46 ins., which are capable of transmitting from 3 to 1,200 horse-power at speeds from 10 to 1,500 revolutions per minute. The power transmitted varies directly as the revolutions.

Coil Clutch.

The clutch shown in fig. 50 consists of a bushed driving plate (*c*) mounted on a shaft and having lugs cast on its face to engage the transmitting coil (*a*). A drum (*b*) of chilled material is keyed to the shaft adjacent to the driving plate. The transmitting coil (*a*), of special steel, having a highly-finished internal surface, is mounted on the drum and has one end engaged with the driving plate lugs, whilst the other is free to be operated. A sliding member (*d*) is mounted on the shaft beyond the drum, its function being to pull the free end of the coil through a steel lever (*e*), which is pivoted on an extension of the driving plate (*c*), and engages the free end of the coil.

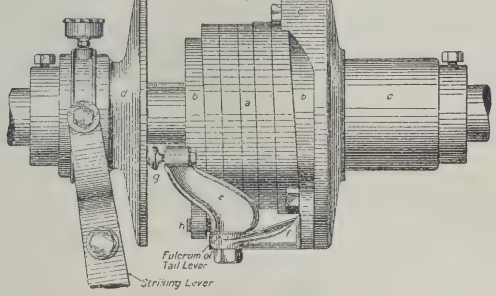


Fig. 50.

In engaging the clutch, the plate (*d*) is moved towards the drum, thereby tilting the lever (*e*) and tightening the free end of the coil, which is contracted and gradually tightens on to the drum (*b*), causing the different members of the clutch to be locked together. The action is similar to that of a man tightening the free end of a rope on a revolving capstan.

The clutch, made by the Coil Clutch Co. Ltd., Johnstone, is simple in construction and compact, and is used in colliery haulage gear, heavy cranes, and rolling mills.

The Wallace Patent Centrifugal Multi-groove Clutch.

(British Hele-Shaw Patent Clutch Company Ltd., Oldham.)

This clutch (fig. 51) transmits power by the action of slipper blocks acted upon at speed by centrifugal force, thus creating frictional contact with the interior face of the clutch, and developing driving power rapidly as the speed increases. The patent lies in the use of grooves on the friction surfaces, giving superior grip over flat faces, and also in the fact that lubricant is introduced which preserves the wearing surfaces, and ensures smooth action and long service.

The clutch consists of a spider—mounted on the motor as the driver portion—which carries on radial guides four movable slippers, which, by centrifugal force, transmit the drive to the case with its dust- and oil-tight cover. The clutch is spring-controlled.

When the clutch begins to drive at just over three-quarter speed the oil collects in special groove extensions, leaving the friction surfaces practically dry at full speed, thus preventing further slippage. For quick pick-up little oil is used, for later pick-up more oil.

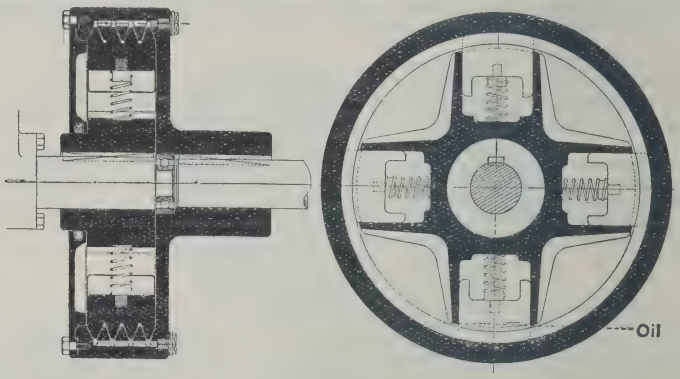

FIG. 51.

The great advantage of the clutch lies in the fact that the motor can start under no load, and as speed is developed the load is applied gradually and automatically, thus reducing strain and wear and tear. The use of the clutch on three-phase motors of the squirrel-cage type cuts down the initial heavy draught on the line and so facilitates starting.

These clutches are particularly adaptable and valuable in starting up individually driven machines under full load. In these cases one part of a centrifugal coupling clutch is mounted on the armature shaft and the other part is mounted on the machine shaft, thus giving perfect connection, reduced starting strain, and driving at full speed like a solid coupling.

For group driving, clutches built within a pulley and mounted on the motor shaft give perfect connection where belt or rope pulley is required. In these cases the clutch case generally forms the pulley, the whole running on ball bearings.

The clutches are made in sizes from 4 ins. to 36 ins., or as required.

Magnetic Clutches.

These consist of two members—the field or driving member, which carries the magnetising winding, and the armature, or driven member. In the design, by the Igranic Electric Co., shown in fig. 52, these members are carried on the face of annular spring steel plates attached to the

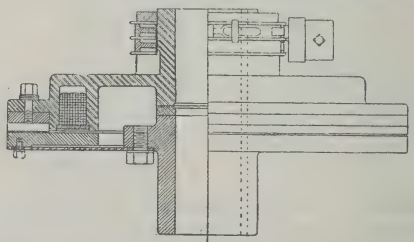

FIG. 52.

driving and driven hubs. Normally the members are held apart, but when the current is supplied so the windings of the field member they are magnetically drawn together, the flexibility of the spring steel plates allowing the necessary movement. The power is then transmitted entirely by

the friction. The engaging surface, fitted externally to the poles of the field member, is composed of woven asbestos and brass wire, and stands proud of the pole faces so as to prevent these coming into contact with the armature. This type of clutch can pick up the load gradually, and can be controlled from remote positions.

Note on Clutches.

In selecting a clutch, attention must be given to the starting torque required in overcoming the inertia of the part, means of stopping quickly in case of accident, and the effect of centrifugal forces on engaging parts in retarding their release or in throwing the members out of action.

Friction Surfaces.

In friction clutches the mating surfaces are sometimes of special materials in order to increase the grip. These materials are usually secured to the body of the clutch by pins, and trouble occasionally arises through the pins shearing. Preferably the fabric should be secured to the body with brass bolts. For low speeds and light pressures wooden surfaces are very suitable, but under opposite conditions the wood becomes charred. When the mating surfaces are of steel one of these should be casehardened. Steel should not be used with cast iron unless the latter has been chilled. In general, close-grained cast iron on cast iron gives the best results. A soft material should not be used with a metal which tends to crumble, as hard particles of the latter get imbedded in the former, and severe scoring results.

(*Professor Dempster Smith.*)

Ferodo Friction Linings.

(*Ferodo Ltd., Chapel-en-le-Frith.*)

Ferodo Brake and Clutch Linings are fabrics of distinct forms, i.e. fibre cotton base, and bonded asbestos, the object and use of each being to provide a surface which in rubbing contact with metal gives a high coefficient of friction which rises with the temperature and is not physically affected by the presence of oil or water—in fact, a damp or greasy surface improves the durability of Ferodo friction linings, but decreases their frictional value in proportion to the quantity and nature of the lubricant present.

Tests on Ferodo fibre prove the average coefficient of friction to be 0·5; the maximum obtained being 0·7—the temperature limit for the fabric being about 230° F.; the material has great mechanical strength and wearing qualities.

Tests on Ferodo bonded asbestos prove the average coefficient of friction to be 0·3 and that the efficiency of the fabric is maintained at any temperature up to 500° F. (260° C.).

Ferodo Fabrics form linings which do not score or seize under any speed or pressure and allow a smooth gradual engagement against dry metal surfaces. The high coefficient of these materials renders very fine angle cones unnecessary. The angles recommended range between 24° and 34° (included).

For flat-plate clutches, Ferodo Friction Linings are made up in the form of circular discs, either jointless or with a close butt joint stretched with fine soft metal wire.

Chekko Friction Linings.

(*Cresswell's Asbestos Co., Ltd., Wellington Mills, Bradford.*)

These linings are made from 100 per cent. pure long asbestos fibre woven into brass wire in one solid piece. They are made in sheet from 2 in. to 12 in. wide, and in thickness varying from $\frac{3}{32}$ in. to $\frac{3}{4}$ in. The sheeting when cut to the required size is fastened to wood foundation blocks by means of counter-sunk brass screws, which screw into metal nuts, the latter lying in slots cut in the wood. In the case of a steel band being lined with the material, screws pass through the band and screw into nuts on the outside of the band, or aluminium rivets may be used for the purpose.

The average coefficient of friction of Chekko is given by the makers as 0·35 against cast iron or steel.

Flat-plate Chekko clutch rings are made up in the stitched joint circular rings or discs hydraulically moulded, and also supplied cut from sheets.

SECTION XIX

PART II

CHAIN GEARING.

(Association of British Driving Chain Manufacturers (A.B.D.C.M.).)

[NOTE.—The British Standard Dimensions for Steel Roller Chains and chain wheels and the clauses relating thereto, contained in Specification No. 228—1925, were adopted by the British Engineering Standards Association from a report presented by the Association of British Driving Chain Manufacturers, which co-operated throughout in the preparation of the Specification.]

The adaptability and high efficiency of chain gearing for the transmission of power is now extensively recognised. Although the advantages of chain driving are not yet fully appreciated, the attention of power users and engineers when considering methods of transmission should be directed towards embodying chain drives of suitable type.

Although belts, ropes, and the several forms of toothed wheel gearing will always have their place, chain drives can in many cases be employed with greater advantage. Chain gearing ensures a positive transmission, at the same time affording a beneficial measure of elasticity. The average efficiency of a well-designed chain drive when new is 99 per cent., and the loss of power will not exceed about 2 per cent. at the end of its useful life. Thus, chain gearing has a higher maintained efficiency than any other form of transmission.

The initial tension required with a belt is unnecessary with a chain, and the bearing friction due to it is therefore eliminated.

Chain drives can be used under very varying conditions in respect of:—(*a*) Speed ratios, which can be readily modified; (*b*) centres of shafts (chain gearing can be used at centres which are too long for spur gear and too short for belts or ropes); (*c*) nature of the load; (*d*) temperature; (*e*) humidity; (*f*) power to be transmitted.

TYPES OF CHAINS.

The two general typeg of power transmission chains are shown by figs. 1 and 2. Speaking generally, the Inverted Tooth type is employed where silence is a consideration, and the Bush Roller type for general applications.

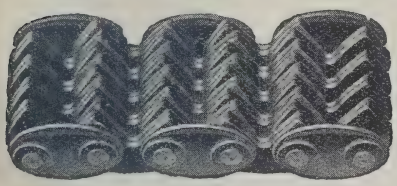

FIG. 1.—Inverted Tooth Type.

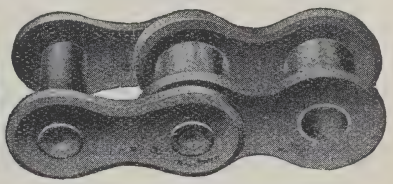

FIG. 2.—Roller Type.

Desirable Conditions for Application of Chain Gearing.

The following statement, prepared by the Association of British Driving Chain Manufacturers, shows the approximate limits that usually obtain in the economical application of chain gearing; where proposed drives are not within these limits, the chain manufacturer should be consulted.

Gear Ratio (maximum): Roller Type, 7 : 1; Inverted Tooth Type, 7 : 1.

Chain Speed.

Normal maximum, assuming the number of teeth is 19.

Pitch.	Roller type. Feet per min.	Inverted tooth type. Feet per min.
Up to ½ in. pitch	1,000	1,500
⅝ in. and ¾ in. ,,	1,000	1,400
1 in. and 1¼ in. ,,	900	1,350
1½ in. and 1⅝ in. ,,	900	1,300
2 in. and 2½ in. ,,	800	1,250
3 in. ,,	700	1,200

Number of Teeth in Wheels.

Minimum	Roller type 17	Inverted tooth type 19
Maximum	,, 120	,, ,, ,, 134

This applies only to inverted tooth chains with a profile based on a 60° link face angle.

In cases where the chain speed is substantially less than shown above, for any given pitch, the number of teeth in the pinion may be reduced, but it must be borne in mind that within limits the greater the number of teeth in pinion the longer will be the life, and the higher the efficiency, of the drive.

Centre Distance between Shafts.

The following expression gives limiting values of centre distance for drives running under ordinary conditions with steady loads, at chain speeds between 1,500 and 300 feet per minute:

$$\text{Maximum centres (in feet)} = 20 \sqrt{\frac{\text{teeth in wheel}}{\text{r.p.m. of pinion}}}$$

Where the chain speed is less than 300 feet per minute, the centre distance should not exceed:

$$\tfrac{1}{2}\sqrt{\text{Pitch} \times \text{teeth in wheel} \times \text{teeth in pinion}}.$$

The values will hold up to inclinations of 60° when the wheel is above the pinion, and up to inclinations of 45° when the pinion is above the wheel; for greater inclinations than these, for impulsive or irregular loading, or where any special considerations enter into the installation or running of a drive, the chain manufacturer should be consulted.

(*a*) *Desirable Minimum.*—The centre distance should be such that the arc of contact between the chain and any wheel is not less than 120°, and with at least 7 teeth in engagement.

(*b*) *Adjustment.*—It is advisable to provide suitable means for the adjustment of the centre distance, and the normal minimum amount of this adjustment should be 1½ times the pitch of the chain.

In some cases adjustment can only be obtained by the use of a jockey wheel, which must engage with the slack side of the chain and have machine-cut teeth.

(*c*) *Chain Length.*—It is desirable that the number of pitches in the chain should not be a multiple of the number of the teeth in either the pinion or the wheel.

Disposition of Drives and Direction of Rotation.

It is preferable that the positions of the driving and driven shafts shall be such that the slack or non-driving free length of the chain will not be inclined at a greater angle than 60° to the horizontal, otherwise adjustment will have to be made frequently.

Drives should be so arranged in relation to the direction of rotation of the shafts that the tight or driving free length of the chain will be uppermost.

Subject to the foregoing, it is preferable when chain cases are fitted that the pinion should be above the wheel.

Clearance.

The normal allowance for clearance over the back of a chain mounted upon a wheel is an amount equal to half the pitch of the chain. When, however, a chain case is fitted an extra amount of clearance above this should be allowed.

The clearance for sag should be greatest at a point somewhere midway along the free portions of the chain, and this clearance should be allowed for both above and below each free portion of chain.

The minimum amount of clearance is

$$\frac{\text{Centre distance between wheels (in inches)}}{12} + \tfrac{1}{4} \text{ in.}$$

The width inside a chain case, and therefore the amount of clearance at the sides of the chain, will frequently be determined by the width of the wheel boss; where this condition does not obtain, and for drives where no case is fitted, a minimum clearance of $\frac{3}{8}$ in. plus $\frac{1}{8}$ in. per foot of centre distance should be allowed.

The clearance between the rivets of inverted tooth chains running in multiple should be $\frac{3}{8}$ in. for pitches up to and including $\frac{3}{4}$ in.; for 1 in. pitch and upwards allow $\frac{1}{2}$ in.

Lubrication.

The provision of chain cases is advisable for all drives where the chain speed exceeds 1,000 ft. per minute, and for drives below this speed when the surrounding air is charged with particles which may adhere to the chain.

Efficient lubrication of chains is of the utmost importance and is, needless to say, more easily obtained where drives are encased.

Drives with a chain speed in excess of 1,350 ft. per minute, those employing a wide chain, or more than one chain, should be fitted with the sump type of chain case, and a pump to deliver oil to the working face of the chain. For lower speeds and narrow chains it will be sufficient to provide an oil-bath case and allow the chain to dip into the oil whilst running.

A drip feed lubricator delivering oil to the inner face of inverted tooth chains, or between the inner and outer plates of roller chains, may be used when the chain speed is not greater than 1,000 ft. per minute. A splash guard should then be fitted to prevent the oil being thrown on to adjacent objects. One drip should be provided for each 3 in. width of inverted tooth chain, and 2, 3, or 4 drips for roller chains, depending upon whether a single, a duplex, or a triplex chain is used.

Erection.

Chain wheels must be rigidly mounted on shafts which are parallel and truly horizontal, and the teeth of the wheels must be in correct alignment.

Where possible, wheels should be placed close to bearings, and must run true on their shafts.

Care should be taken that the chain connection is properly secured.

Before starting up the drive the chain should be lubricated and centres adjusted to take up any undue slack. No tension should be put upon the chain.

Maintenance.

Periodic examination is advisable to ascertain:

(*a*) If correct alignment of the wheels has been maintained; (*b*) if undue wear is taking place; (*c*) if adjustment of chain is needed; (*d*) if the chain requires cleaning; (*e*) if lubrication is being effectively carried out.

Improved service usually results when chains are removed from time to time for cleaning. They should be washed with paraffin and, after draining, thoroughly lubricated before being again used.

When replacing worn chains by new ones always ascertain that undue wear has not taken place on the teeth of the wheels.

A.B.D.C.M. STANDARDS FOR ROLLER CHAINS.
'SHORT PITCH' SERIES. (0·375 – 0·75 in. PITCHES.)

TOOTH CUTTER FORMS.

For the convenience of chain users and to ensure complete interchangeability, the Association has standardised tooth forms which, while not being identical with any of the existing forms,

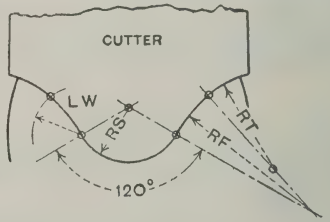

FIG. 3.

incorporate the essential features of each. The general construction is shown in fig. 3. It consists of a *roller seating*, *working faces*, and *topping curves*, all of which are arcs of circles.

The angle of 120° subtending the roller seating has its origin at the centre of the diameter of the roller seating. The working faces are comparatively flat curves tangential to the roller seating, and the topping curves are tangential to the working faces and of such a radius as to give a suitable height of tooth. The dimensions of tooth forms for the Association Standard Chains are given in the following table:

Roller Diameter.	Cutter No.	No. of Teeth to Cut.	R.S. Radius of Roller Seating.	R.F. Radius of Working Face.	L.W. Length of Working Face.	R.T. Radius at Top of Tooth.

All dimensions are in inches.

Wheels.

It is of the utmost importance that chain wheels should have their teeth accurately machined with cutters of correct form. Pinions should preferably have an odd number of teeth to equalise wear on the chain.

(*a*) *Section Profile of Teeth for Roller Chains.*—Chain wheel blanks should be machined as indicated in fig. 4.

Roller Chain Wheels Tooth Profile.

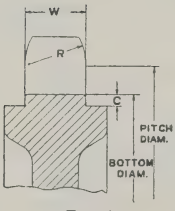

FIG. 4.

Pitch diam. . . .	= Chain pitch cosec $\frac{180°}{\text{Number of teeth.}}$
Bottom diam. max.. .	= Pitch diam. minus max. roller diam.
Tolerance on bottom diam.	= Minus 0·001 in. per 1 in. pitch diam., but in any case to be within the following limits: min., 0·005 in.; max., 0·020 in.
W (mean width of tooth)	= (95 % of width between chain inner plates), minus 0·01 in.
Tolerance on W . .	. ± (1 % of width between chain inner plates), plus 0·002 in.
R (Tooth side radius)	. = Roller diameter.
C (minimum shroud depth)	= $\frac{\text{Chain pitch} - \text{R}}{2} + \frac{0{\cdot}8 \text{ pitch}}{\text{Number of teeth.}}$

Measuring Loads.

To ensure interchangeability of chains it is necessary that measurements be taken under similar conditions.

It is, therefore, necessary that chains be measured before oiling, but after the test load of one-third the breaking strength has been applied, and that at the time of measurement the chain should be supported horizontally throughout its entire length.

As the necessary load should bear a definite relation to the breaking load of the chain, and inasmuch as actual breaking loads, in practice, are approximately in the ratio of pitch^2, the measuring load is taken as equal to (Pitch^2 × 112) lbs. For the ' long pitch ' series the measuring loads are the same as for the ' short pitch ' series of corresponding strength.

Measuring Length and Tolerance.

The actual length of test chains for measuring purposes is taken as 50 pitches for all pitches of chain, and a tolerance of 0·1 per cent. per pitch per length of 50 pitches is allowed in excess of the theoretical length.

'Long Pitch' Series.

A standard ' long pitch ' series of chains is formed from the standard series by using rollers, bushes, and rivets of a given pitch, but with inner and outer plates having twice the pitch.

Profiles of Teeth.

As for standard series of roller chains, but based on half the nominal pitch of a long pitch chain.

Cutters.

As for standard series of roller chains. (That is, for a given roller diameter a standard cutter may be employed for both standard or long pitch chains.)

RENOLD
CHAIN DRIVES

COMPLETE Chain Drives from 1 to 100 h.p. are available from stock, and quick despatch can be given on drives up to 1,000 h.p.

The Morse Rocker-Joint Chains.

(The Morse Chain Co. Ltd., Letchworth, Herts.)

These chains, fig. 5, form an important departure in silent chain driving. Until their introduction the principal objection to chains was found in the rapid wear and consequent stretch. This is necessarily present with all chains having round joint-pins, friction due to sliding surfaces

Fig. 5.

Fig. 6.

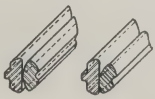

Fig. 7.

being unavoidable. A very ingenious feature is the joint, which in its latest development, as shown in fig 7, consists of two pieces, i.e. the rocker and seatpin, the former being provided with a knife edge which rocks on the face of the latter when the joint passes on or off the wheel. The bearing surface extends throughout the width of the chain. The pins for all practical purposes

are an integral part of the link, fig. 6, hence the only motion which takes place at the joint is a rocking movement. This ensures absence of sliding friction, which means the reduction of wear at the joint to the minimum, with consequent maximum life and efficiency. The shape of the tooth permits silent running, even under high speed.

Another important departure in the Morse chain drive is that represented by the No. 25 reinforced type chain—shown in fig. 8. In this construction the outer links are all knit together by short rivets and spacing pieces, adding very considerably to the material strength of the chain; also distributing the load more equally, and enabling the chain to run at higher speeds than has hitherto been possible.

The greatest ratio of gearing under favourable conditions with the Morse chains is 10 : 1. The following table gives the various pitches manufactured and the maximum permissible R.P.M. (revolutions per minute) for each:

Max. R.P.M. .	4,000	2,000	1,600	1,400	1,100	1,000	800	700	600	500	400	250
Pitch in ins. .	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	·9	1	1·2	1·25	1·5	1·75	2	3

The chain width depends on the speed, determined as follows:—

$$\text{Speed} = \frac{N \times P \times \text{R.P.M.}}{12} = \text{F.P.M.} \qquad \text{Load} = \frac{\text{H.P.} \times 33{,}000}{\text{F.P.M.}} = \text{total load on chain in lbs.}$$

where,

H.P. = Maximum horse-power; P = Circular pitch in inches;
N = No. of teeth; F.P.M. = Feet per minute.

This total load divided by the load per inch width advised gives the width of the chain.

Average permissible loads per inch in width for general machine-shop drives are as follows:—

Lbs. per inch wide .	65	85	105	125	160	200	220	240	300	400	500	800
Pitch in ins. . .	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{3}{4}$	·9	1	1·2	1·25	1·5	1·75	2	3

Good chain speeds or average machine-shop drives are from 1,200 to 1,500 ft. per min.

As no friction due to sliding surfaces takes place, however, the chains can be run at speeds which would, owing to centrifugal force, throw off all lubricant, and drives of this make are now transmitting light loads satisfactorily at 3,000 ft. per min. chain speed.

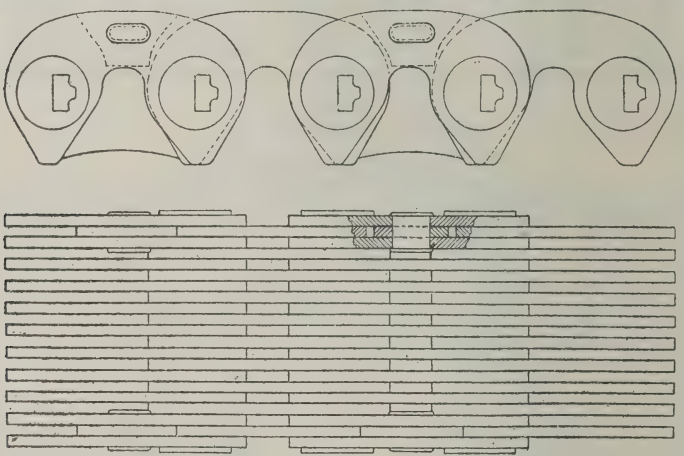

FIG. 8.

In view of its special joint construction, the Morse chain is claimed to surpass all others in point of size and strength, and the fact of being able to manufacture so large a size of silent chain as the 3-in. pitch in widths up to 24 ins. has resulted in such chain drives being applied for transmissions up to even 5,000 h.p. in a single drive.

The Morse chains are made in nineteen different types and pitches and single drives can be furnished for transmitting from $\frac{1}{4}$ h.p. up to 1,000 h.p.

SECTION XIX

PART III

TOOTH GEARING—HELICAL GEARING—TURBINE GEARS—WORM GEARING—VARIABLE-SPEED GEAR.

(Revised by H. T. Davey, A.M.I.Mech.E.)

Definitions.

The '*pitch circle*' is a virtual circle representing the periphery of a disc that would transmit by friction, when in contact with a similar disc, the required relative motion.

'*Base Circle.*'—The generating circle, or circle from which the involute curve is developed, in the case of the involute profile.

'*Diameter of a gear*' is the diameter of the pitch circle, and is often referred to as the pitch diameter.

'*Circular pitch*' is the length of the arc of the pitch circle measured from a point on one tooth to the corresponding point on the next tooth. It is equivalent to the circumference of the pitch circle divided by the number of teeth in the gear.

'*Diametral pitch*' is the number of teeth for each inch of pitch diameter, and is equivalent to the number of teeth in the gear divided by the diameter. It is a ratio and not a dimension. If a gear has a pitch diameter of 4 ins. and has 40 teeth, then it has a diametral pitch of 10.

'*Module*' is the reciprocal of the diametral pitch, and hence represents the pitch diameter per tooth. The module multiplied by the number of teeth gives the pitch diameter. The module is commonly used in Europe where the metric system is universal.

'*Chordal pitch*' is the length of a straight line drawn from the pitch line centres of two contiguous teeth.

'*Addendum*' is the height of a gear-tooth outside the pitch circle or pitch line.

'*Dedendum*' is the depth of a tooth space below the pitch circle or pitch line.

'*Clearance*' is the distance allowed between the top of the tooth of one gear and the bottom of its mating tooth space. It is equal to the difference between the addendum and the dedendum.

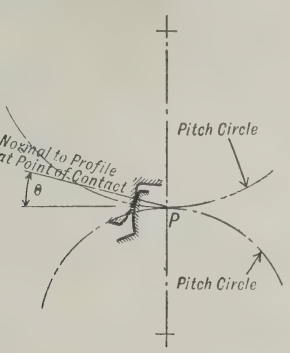

FIG. 1.

'*Whole depth*' is the total distance measured radially between circles containing the periphery of the teeth and the bottom of the tooth spaces.

'*Working depth*' is the distance which the teeth of one gear extend into the spaces of its mating gear. It is equal to the whole depth minus the clearance, and is also equal to the sum of the addenda of two mating gears.

'*Active profile*' is that part of the tooth which actually comes into contact with the profile of its mating tooth.

'*Line of action*' (see fig. 1).—In properly formed gears a line normal to the point of contact of two engaging teeth passes through the pitch point P. All points of contact of engaging teeth should fall on this line in order to secure uniform transmission of motion, for involute gears.

'*Angle of obliquity of action*,' θ (fig. 1), is the angle made by the intersection of the line of action with the tangent at P.

'*Interference*' occurs when points of contact of mating teeth do not fall on the line of action. Motion cannot be uniform under those conditions.

'*Width of tooth face*' is the length of the surface of contact of two mating gears. It is usually equal to the full width of the gear-wheel.

'*Centre distance*' is the linear measurement between the centres of two mating gears.

'*Line of centres*' is that line containing the centres of two mating gears.

A '*trundle*,' '*lantern pinion*,' or '*wallover*,' is a pinion the teeth of which are formed by round bars or rods of equal length, the ends of which are inserted in two discs, mounted centrally on a spindle. Such a pinion will operate wheels having, within limits, any number of teeth.

A '*hunting tooth*' or '*cog*' is an odd tooth provided in a wheel in order to secure uniformity in the wear of the teeth. If the number of teeth in the wheel is exactly divisible by the number of teeth in the pinion, then the same teeth are continually coming into engagement. This tends to produce uneven wearing, and hence, in mill gearing particularly, it is usual to introduce the hunting tooth. In accurately cut steel gears the same difficulties do not so readily arise.

'*Minimum number of teeth*' in a *pinion*.—Pinions having less than 10 teeth should not be used generally for power transmission. In cases where size is a very important controlling factor, then pinions having as few as 5 teeth can be made to engage sufficiently well. In such cases, however, the involute tooth profile must be continued practically to the root of the tooth, the standard tooth form being quite unsuitable. Such conditions imply a high-pressure angle.

FORMS OF GEAR TEETH.

Involute Teeth.

The involute tooth profile is now widely used, since it presents several important advantages compared to the older cycloidal form.

Three involute systems are in vogue: the standard 14½° involute system, the 20° full depth tooth system, and the 20° stub tooth system. The former system is a compromise between the cycloidal and involute tooth forms. Actually very little of the profile is involute. The need for smaller numbers of teeth and greater accuracy in the gears led to the introduction of the 20° full depth system. Such gears have stronger teeth, less undercutting being required in gears with few teeth.

In these two forms gears are interchangeable, and any two wheels of the same pitch will run together, provided the centre distance is suitable, irrespective of the number of teeth.

20° stub teeth have reduced tooth height, and the general proportions are different. The teeth are stiffer than those of the former types.

Gears having involute tooth profiles have the advantage that should the wheel centres be slightly inaccurate the teeth will still mesh properly. This occurs due to the fact that the path of contact is a straight line tangential to the base circle. The effect of excessive wheel centre distance increases the angle of obliquity producing increased back lash and pressure on the bearings.

Since the two engaging surfaces in contact are convex the surface is small, and hence the wear on involute teeth is rather greater than is the case with cycloidal teeth.

With a 14½° angle of obliquity and the standard addendum of $0{\cdot}318p$, excessive relative sliding occurs at the tooth points and local wear becomes very pronounced. Further, a 12-toothed pinion gearing with a rack having straight teeth, with a 29° included angle between the working faces, produces severe interference between the pinion flanks and rack tooth points. The cutting away of the teeth to obviate this defect reduces the path of contact, which is a further disadvantage. If the two angles are adhered to, then the shape of the engaging teeth needs some modification in the case of pinions having a small number of teeth. Actually the flanks of the pinion teeth are usually made radial under such conditions, and the rack tooth faces are rounded off.

The trouble referred to can be obviated by using 20° or 22½° angles of obliquity, when under such conditions the true tooth profile can be used without fear of interference.

The effect of increasing the angle of obliquity to 20° or 22½° is to increase the pressure on the bearings by 4 to 6 per cent.

With a pinion of 28 teeth and 14½° pressure angle interference is avoided, as is also the case with a 20-tooth pinion having a 20° angle of obliquity. With small numbers of teeth interference can be avoided if the stub teeth proportions are adopted for the addenda. With such teeth the efficiency of transmission is increased, due to a better rolling action in preference to the sliding action, which occurs when teeth have too great an addendum.

Setting out Involute Teeth.

Let ABCD (fig. 2) be the pitch circles of two mating gears, and EF their line of centres. Through the intersection of the two pitch circles with EF, draw MN such that angle θ is equal to the angle of obliquity of action desired. MN is the line of action of the two gears,

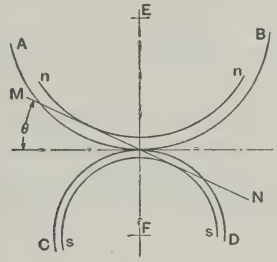

FIG. 2.

and is therefore the common tangent to the two base circles from which the teeth profiles are developed. Hence, with centres on EF draw the base circles *nn* and *ss*, just touching the line MN. The teeth profiles can then be set out as follows: Let A be the base circle of the gear and K the generator, which in effect is a straight edge (see fig. 3). Cut a notch in the edge of K and fix a

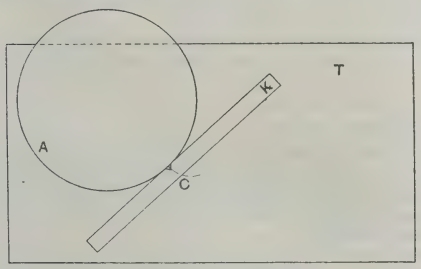

FIG. 3.

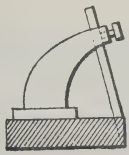

FIG. 4.

steel point in a clamp, as shown in fig. 4, so that the point touches the circle A through the notch. Press the straight edge up to circle A and steadily roll straight edge round circle. If a piece of finely sand-papered tin T is placed beneath as shown, a curve will be traced on it, as K rolls, shown at C. This is the tooth profile.

Proportions of Involute Gear-Teeth for Spur Gearing.

(Machine-cut gears of 14½° and 20° obliquity.)

(*Messrs. Brown and Sharpe.*)

p = circular pitch; $d.p.$ = diametral pitch.

Thickness of tooth and width of tooth space	$0{\cdot}5p$ or $1{\cdot}571/d.p.$	Dedendum	$0{\cdot}368p$ or $1{\cdot}157/d.p.$
Addendum	$0{\cdot}318p$,, $1/d.p.$	Bottom clearance	$0{\cdot}05p$,, $0{\cdot}157/d.p.$
		Total height of tooth	$0{\cdot}686p$,, $2{\cdot}157/d.p.$

Proportions of Short Involute Teeth.

(Stub teeth, 20° obliquity.)

Thickness of teeth and width of space	$0{\cdot}5p$ or $1{\cdot}571/d.p.$	Working height	$0{\cdot}5p$ or $1{\cdot}571/d.p.$
Addendum	$0{\cdot}25p$,, $0{\cdot}785/d.p.$	Total height of tooth	$0{\cdot}55p$,, $1{\cdot}728/d.p.$
Dedendum	$0{\cdot}3p$,, $0{\cdot}942/d.p.$	Clearance	$0{\cdot}05p$,, $0{\cdot}157/d.p.$

Rolling-Mill Gears.

The shape of the teeth for this purpose varies somewhat from the standard involute form, although the involute profile is closely followed. Good radii are provided at the root of the teeth, and a $22\frac{1}{2}°$ pressure angle is used. Usually the tooth face is exceptionally wide, often being made equal to the pitch diameter of the gear. This makes provision for the heavy wear to which these gears are subjected.

Typical tooth proportions are as follows:—

Addendum, $0 \cdot 275p$; dedendum, $0 \cdot 325p$; width of tooth at pitch circle, $0 \cdot 42p$.

Machine-Moulded Teeth.

Proportions for these vary. The following are typical values:—

Thickness of tooth, $0 \cdot 485p$. Width of tooth space, $0 \cdot 515p$. Addendum, $0 \cdot 25p$ to $0 \cdot 35p$. Dedendum, $0 \cdot 35p + 0 \cdot 08$ in. to $0 \cdot 4p + 0 \cdot 08$ in. Total height of tooth, $0 \cdot 6p + 0 \cdot 08$ in. to $0 \cdot 75p + 0 \cdot 08$ in.

Cycloidal Teeth.

Small amount of wear occurs with this form of tooth profile due to large surface of contact. To ensure quiet running and no back lash it is essential that the wheel centres be accurately located, since the path of contact consists of two curves which change direction at the pitch point.

These gears are difficult to cut accurately in a machine, and if the profiles of pinions of 12 teeth to a rack are generated with rolling circles greater in diameter than half the diameter of the smallest pinion, then the flanks cannot be cut by the ordinary rotating cutter.

Gears of this form have good wearing qualities, but the advent of higher speeds of rotation have made the defects of these teeth very pronounced, and involute gears have superseded them.

Epicyclic Gears.

In epicyclic gearin the arm rotates, and hence its motion must be added to that of the wheels. In general, the action of epicyclic gear trains can be summarised as follows:—the number of revolutions of any gear-wheel in the train for each single revolution of the arm is equivalent to the number of revolutions that the gear-wheel would make if the arm was fixed and the first gear-wheel turned through 1 revolution + 1 for wheels rotating in the same direction, and − 1 for wheels rotating in the reverse direction to that of the arm.

If 'n' is the number of gears in a train, then the nth gear-wheel will rotate in the *same direction* as the arm if 'n' is an *even number*, and in the reverse direction if 'n' is odd and the velocity ratio greater than 1. If the velocity ratio is less than 1, then direction of rotation is the same as that of the arm, 'n' being odd.

With epicyclic gears high velocity ratios can be obtained in a convenient form.

Involute Gear Cutters.

Since the dimensions of gear teeth are proportional to the circular or diametral pitch in the standard tooth forms, it follows that, theoretically, a different cutter is required for gears having different numbers of teeth.

In actual practice, however, a set of 8 cutters is employed for the $14\frac{1}{2}°$ system, and another set of 8 for the 20° system.

The cutters are employed as follows and are numbered from 1 to 8, each one being known by its particular number:—

No. 1	for cutting gears having	135	teeth	to a rack			
No. 2	,,	,,	,,	,,	55	,,	134 teeth
No. 3	,,	,,	,,	,,	35	,,	54 ,,
No. 4	,,	,,	,,	,,	26	,,	34 ,,
No. 5	,,	,,	,,	,,	21	,,	25 ,,
No. 6	,,	,,	,,	,,	17	,,	20 ,,
No. 7	,,	,,	,,	,,	14	,,	16 ,,
No. 8	,,	,,	,,	,,	12	,,	13 ,,

The shape of the cutter conforms to that of the gear having the smallest number of teeth.

The above cutters are satisfactory for gears working under general conditions where special attainments are not needed, and for gears working under steady loading conditions.

For more accurate work and more precise conditions, cutters bearing half numbers are made as follows:—

No. 1½	for cutting gears having		80	teeth to	134	teeth
No. 2½	,,	,,	,,	,,	42	,,	54 ,,
No. 3½	,,	,,	,,	,,	30	,,	34 ,,
No. 4½	,,	,,	,,	,,	23	,,	25 ,,
No. 5½	,,	,,	,,	,,	19	,,	20 ,,
No. 6½	,,	,,	,,	,,	15	,,	16 ,,
No. 7½	,,	,,	,,	,,	13 teeth only		

Spur Gear Calculations.

Relation between circular pitch and diametral pitch.

c.p. = circular pitch; *d.p.* = diametral pitch; *p.c.d.* = pitch circle diameter. N = number of teeth; $\pi = 3{\cdot}1416$.

$$c.p. = \frac{\pi \times p.c.d.}{N}; \quad d.p. = \frac{N}{p.c.d.}$$

Hence,

$$c.p. \times d.p. = \pi; \quad c.p. = \frac{\pi}{d.p.}; \quad d.p. = \frac{\pi}{c.p.}$$

Example: A wheel has 60 teeth of 10*d.p.* What is its *p.c.d.* and *c.p.*?

$$p.c.d. = \frac{60}{10} = 6 \text{ ins.}; \quad c.p. = \frac{\pi}{10} = 0{\cdot}314 \text{ ins.}$$

The Number of Teeth being given and the Diametral Pitch, to find the Outside Diameter of the Blank required for 14½° standard Involute Gear.

RULE.—Add 2 to the number of teeth and divide by the diametral pitch.

EXAMPLE.—No. of teeth 40, *d.p.* 4. Add 2 to the 40, making 42, and divide by 4; the quotient is 10½ ins., which is the required outside diameter of the blank.

The distance between centres of two mating gears is found by adding the number of teeth together and dividing half the sum by the diametral pitch.

If two mating gears have respectively 60 and 40 teeth, add 60 and 40 together, making 100, which divided by 2 gives 50. Assuming the diametral pitch of the gears is 4, 50 divided by 4 gives 12½ ins., the required centre distance.

To determine the Pitch Line Velocity of a Gear.

RULE.—Multiply the pitch circle diameter by π and the product by the number of revolutions per second. Divide the final product by 12, and the result is the pitch line velocity in feet per second.

EXAMPLE.—A wheel of 6 ins. *p.c.d.* runs at 320 revs. per min. What is its pitch line velocity?

$$\text{Pitch line velocity} = \frac{3{\cdot}1416 \times 6 \times 320}{12 \times 60} = 8{\cdot}4 \text{ ft. per sec.}$$

or 504 ft. per minute.

To compute the Circular Pitch of a Wheel.

RULE.—Divide circumference at the pitch line by the number of teeth.

EXAMPLE.—A wheel 40 ins. in diameter requires 75 teeth; what is its circular pitch?

$$\frac{3{\cdot}1416 \times 40}{75} = 1{\cdot}6755 \text{ ins.}$$

To compute the Chordal Pitch.

RULE.—Divide 180° by the number of teeth, ascertain the sine of the quotient, and multiply it by the diameter of the wheel.

EXAMPLE.—The number of teeth is 75, and the diameter 40 ins.; what is the chordal pitch?

$$\frac{180}{75} = 2° 24' \text{ and sine of } 2° 24' = \cdot04188, \text{ which} \times 40 = 1\cdot6752 \text{ in.}$$

To compute the Diameter of a Wheel.

RULE.—Multiply the number of teeth by the circular pitch, and divide the product by 3·1416.

EXAMPLE.—The number of teeth in a wheel is 75, and the circular pitch 1·675 ins.; what is the diameter of the wheel?

$$\frac{75 \times 1\cdot675}{3\cdot1416} = 40 \text{ ins.}$$

To compute the Number of Teeth in a Wheel.

RULE.—Divide the pitch circumference by the circular pitch.

To compute the Number of Teeth in a Pinion or Follower to obtain a given Speed Ratio.

RULE.—Multiply the number of teeth in the driving gear by the speed ratio of the two gears.

EXAMPLE.—A driving gear makes 40 revs. per min., and has 54 teeth. The pinion is to run at 120 revs. per min.; what number of teeth is required?

$$\text{Speed ratio} = \frac{40}{120} = \frac{1}{3}.$$

$$\text{No. of teeth required in pinion} = \frac{54 \times 1}{3} = 18.$$

To compute the Diameter of a Pinion when the Diameter of the Wheel and Number of Teeth in the Wheel and Pinion are given.

RULE.—Multiply the diameter of the wheel by the number of teeth in the pinion, and divide the product by the number of teeth in the wheel.

EXAMPLE.—The diameter of a wheel is 25 inches, the number of its teeth 210, and the number of teeth is the pinion 30; what is the diameter of the pinion?

$$\frac{25 \times 30}{210} = 3\cdot57 \text{ inches.}$$

To compute the Number of Teeth required in a Train of Wheels to produce a given Velocity Ratio.

RULE.—Multiply the number of teeth in the driver by its number of revolutions, and divide the product by the number of revolutions of each pinion, for each driver and pinion.

EXAMPLE.—If a driver in a train of 3 wheels has 90 teeth, and makes 2 revolutions, and the velocity ratios required are 2, 10, and 18, what are the number of teeth in each of the other two?

$$10 : 90 :: 2 : 18 \quad \therefore \text{ teeth in 2nd wheel} = 18$$
$$18 : 90 :: 2 : 10 \quad \therefore \text{ teeth in 3rd wheel} = 10$$

To compute the Circumference of a Wheel.

RULE.—Multiply the number of teeth by their circular pitch.

To compute the Revolutions of a Wheel or Pinion.

RULE.—Multiply the diameter or circumference of the wheel, or the number of its teeth, as the case may be, by the number of its revolutions, and divide the product by the diameter or circumference of the wheel, or number of teeth in the pinion.

EXAMPLE.—A pinion 10 inches in diameter is driven by a wheel, 2 feet (24 inches) in diameter, making 46 revolutions per minute; what is the number of revolutions of the pinion?

$$\frac{24 \times 46}{10} = 110\cdot4 \text{ revolutions.}$$

To compute the Speed of a Pinion.

RULE.—Divide the diameter, circumference, or number of teeth in the driver, as the case may be, by the diameter, etc., of the pinion.

When there are a Series or Train of Wheels and Pinions.

RULE.—Divide the continued product of the diameter, circumference, or number of teeth in the wheels, by the continued product of the diameter, &c., of the pinions.

EXAMPLE 1.—If a wheel of 32 teeth drives a pinion of 10, upon the axis of which there is one of 30 teeth driving a pinion of 8, what are the revolutions of the last?

$$\frac{32}{10} \times \frac{30}{8} = \frac{960}{80} = 12 \text{ revolutions.}$$

EXAMPLE 2.—The diameters of a train of wheels are 6, 9, 9, 10, and 12 inches; of the pinions, 6, 6, 6, 6, and 6 inches; and the number of revolutions of the driving-shaft or prime mover is 10; what are the revolutions of the last pinion?

$$\frac{6 \times 9 \times 9 \times 10 \times 12 \times 10}{6 \times 6 \times 6 \times 6 \times 6} = \frac{583200}{7776} = 75 \text{ revolutions.}$$

To compute the Number of Teeth in each Wheel of a Train for a given Speed Ratio.

The numbers of teeth in the wheels are inversely proportional to the speeds.

EXAMPLE.—What should be the number of teeth in each of three wheels so that the speeds of each are in the ratio of 3 : 2 : 1, the pinion having 18 teeth?

$$\text{No. of teeth in second wheel} = 18 \times \frac{3}{2} = 27.$$

$$\text{,, ,, third ,,} = 27 \times \frac{2}{1} = 54.$$

FORMULÆ FOR DETERMINING THE DIMENSIONS OF GEARS BY THE METRIC PITCH.

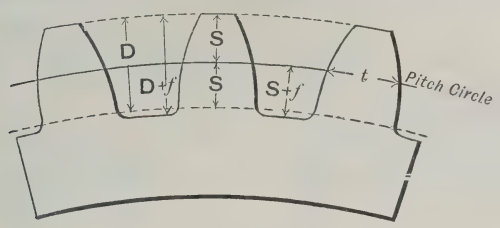

FIG. 5.

M = module; D′ = pitch diameter of gear; D = whole diameter of gear; N = number of teeth in gear; D″ = working depth of teeth; t = thickness of teeth on pitch line; f = amount added to depth for clearance.

Then

$$M = \frac{D'}{N} \text{ or } \frac{D}{N+2}. \qquad D' = NM. \qquad D = (N+2)\,M.$$

$$N = \frac{D'}{M} \text{ or } \frac{D}{M} - 2. \qquad D'' = 2M. \qquad t = M\,1{\cdot}5708. \qquad f = \frac{M\,1{\cdot}5708}{10}.$$

The module is equal to the part marked 'S' in fig. 5, measured in mm. and parts of mm.

RELATION BETWEEN MODULE AND DIAMETRAL PITCH.

Module.	Diametral Pitch.	Module.	Diametral Pitch.	Module.	Diametral Pitch.	Module.	Diametral Pitch.
0·5	50·800	2·5	10·160	6	4·233	14	1·814
0·75	33·867	3	8·466	7	3·628	15	1·693
1	25·400	3·5	7·257	8	3·175	16	1·587
1·25	20·320	4	6·350	9	2·822	17	1·494
1·5	16·933	4·5	5·644	10	2·540	18	1·411
1·75	14·514	5	5·080	11	2·309	19	1·336
2	12·700	5·5	4·618	12	2·117	20	1·270
2·25	11·288			13	1·954		

NOTE.—In the above table the module is worked out in millimetres. By reducing the dimensions to inches the equivalent diametral pitch is obtained.

EXAMPLE.—Module = 0·5, determine equivalent diametral pitch.

$\frac{1}{0·5} = 2$. Since 25·4 mm. = 1 in., ∴ equivalent diametral pitch = 50·800.

Mill Gearing.

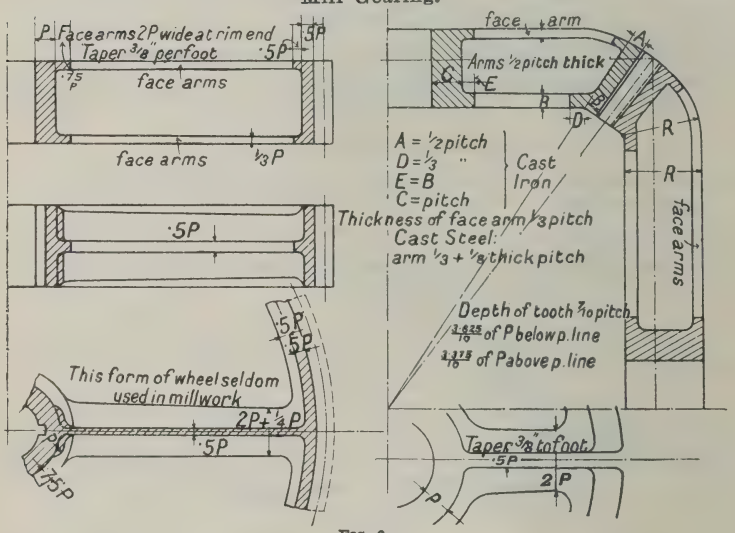

FIG. 6.

Fig. 6 shows the proportions of tooth, arm, faces, bosses, etc., commonly used in mill gearing. (*J. Nuttall.*)

General Method of Determining Dimensions of Gear Teeth to carry a Given Load.

Horse-power (H.P.) to be transmitted by gear $= \frac{WV}{33{,}000}$; W = tangential load at pitch line in lbs.; V = pitch line velocity in feet per min.

$$W = \frac{33{,}000 \times H.P.}{V} \text{ lbs.}$$

In general, it is assumed that the load W is concentrated at the point of the tooth, and the tooth to act as a cantilever.

Hence, if h = height of tooth in ins., f = face width in ins., b = breadth of tooth in ins. at the *weakest section*, s = safe stress for the material used in lbs. per sq. in.

$$Wh = \tfrac{1}{6}fb^2s; \quad f = \frac{6Wh}{b^2s}; \quad b = \sqrt{\frac{6Wh}{fs}}.$$

The breadth of a tooth and its height can be fixed initially, according to general proportions. Usually it is convenient to calculate the required face width to give the required strength.

The safe stress can be calculated from the formula following in connection with the Lewis formula. It will depend upon loading conditions and material used.

Experience has proved that a cast-iron wheel having teeth 3 ins. pitch and a face width of 7½ ins. will transmit at 6·66 ft. per sec. 60 horse-power.

To compute the Horse-Power transmitted by a Gear.

RULE.—Multiply the tangential load in lbs. at the pitch line by the pitch line velocity in ft. per min. and divide the product by 33,000.

EXAMPLE.—A gear 8 ins. *p.c.d.* runs at 400 r.p.m. and carries a pitch line load of 800 lbs. What horse-power is transmitted?

$$\text{Pitch line velocity} = \frac{\pi \times p.c.d. \times N}{12} = \frac{3{\cdot}1916 \times 8 \times 400}{12} = 837 \textit{ ft. per min.}$$

$$\text{H.P.} = \frac{800 \times 837}{33{,}000} = 20{\cdot}3.$$

The Lewis Formula.

(1.)

This formula is in general use for determining gear strength, and is used extensively in design. It was intended for use on machine-cut gears, but with suitable modification can be applied to machine moulded teeth and even ordinary cast gears when suitably modified.

W = safe tangential load at pitch line in lbs.; y = Lewis factor, which depends upon the tooth form; s = safe stress for the material used in lbs. per sq. in.; f = width of tooth face in ins.; p = circular pitch of teeth in ins.

Then

$$W = ysfp.$$

The values of s and y are given in the following tables:—

LEWIS'S VALUES OF s.

Speed in Feet per Minute.	100 or less.	200	300	600	900	1,200	1,800	2,400
Cast iron .	8,000	6,000	4,800	4,000	3,000	2,400	2,000	1,700
Steel . .	20,000	15,000	12,000	10,000	7,500	6,000	5,000	4,300

LEWIS'S VALUES OF y.

Number of Teeth.	Involute (20 deg. obliquity).	Involute (15 deg. obliquity) and Cycloidal.	Radial Flanks.	Number of Teeth.	Involute (20 deg. obliquity).	Involute (15 deg. obliquity) and Cycloidal.	Radial Flanks.
12	0·078	0·067	0·052	27	0·111	0·100	0·064
13	0·083	0·070	0·053	30	0·114	0·102	0·065
14	0·088	0·072	0·054	34	0·118	0·104	0·066
15	0·092	0·075	0·055	38	0·122	0·107	0·067
16	0·094	0·077	0·056	43	0·126	0·110	0·068
17	0·096	0·080	0·057	50	0·130	0·112	0·069
18	0·098	0·083	0·058	60	0·134	0·114	0·070
19	0·100	0·087	0·059	75	0·138	0·116	0·071
20	0·102	0·090	0·060	100	0·142	0·118	0·072
21	0·104	0·092	0·061	150	0·146	0·120	0·073
23	0·106	0·094	0·062	300	0·150	0·122	0·074
25	0·108	0·097	0·063	Rack	0·154	0·124	0·075

The values for s will depend upon pitch line velocity, and can be selected from the above table or can be determined from the following formula :—

$$S_v = S_o \left(\frac{600}{600 + V}\right) \quad \text{NOTE:—SEE ADDENDUM.}$$

where,

S_v = Safe stress at given pitch line velocity in lbs. per sq. in.; S_o = Safe stress at basic velocity in lbs. per sq. in.; V = Actual pitch line velocity in ft. per min.

Suitable values for S_o.—Nickel-chrome gears, 100,000 lbs. per sq. in.; steel-cut gears, 20,000 lbs. per sq. in.; cast iron, 8,000 lbs. per sq. in.

When serious shock loads are likely to occur, or when alternations in load occur, the above values must be modified accordingly.

EXAMPLE.—A mild steel gear having a pitch circle 6 ins. diameter is to transmit 20 horse-power at 400 revs. per min. Determine the required pitch and width of face.

$$\text{Velocity of pitch line} = \frac{\pi \times 6 \times 400}{12} = 628 \text{ ft. per min.}$$

$$S_v = S_o \left(\frac{600}{600 + V}\right) = \frac{20{,}000 \times 600}{1228} = 10{,}000 \text{ lbs. per sq. in. approx.}$$

$$W = \frac{33{,}000 \times \text{H.P.}}{V} = \frac{33{,}000 \times 20}{628} = 1{,}052 \text{ lbs.}$$

Assume value of y for 20 teeth = 0·09 and width of face = $3p$.

$$W = ysfp\,; \quad 1{,}052 = 0{\cdot}09 \times 10{,}000 \times 3p^2.$$

$$p = \sqrt{\frac{1{,}052}{0{\cdot}09 \times 10{,}000 \times 3}} = \tfrac{5}{8} \text{ in. circular pitch } (0{\cdot}625).$$

Check number of teeth since originally number was assumed.

$$\text{No. of teeth in gear} = \frac{\pi \times p.c.d.}{c.p.} = \frac{3{\cdot}1416 \times 6}{0{\cdot}625} = 30$$

Actual pitch circle diameter would be $\dfrac{30 \times 0{\cdot}625}{\pi} = 5{\cdot}968$ ins.

Width of face = $3p = 1\tfrac{7}{8}$ in.

From the table of values of y its value for 30 teeth is greater than that for 20 teeth, the assumed value. Hence the actual safe load for the gear is a little greater than is required. In cases of considerable differences fresh values of y must be chosen, and the calculation for pitch repeated.

MODIFICATION OF LEWIS FORMULA.

By H. T. Davey, A.M.I.Mech.E.

(2.)

For the application to gearing problems where it is intended to use circular pitches,

$$W = ysfp.$$

For similar problems where it is intended to use diametral pitches,

$$W = \frac{zsF}{P}$$

where,

W = Safe tangential load at pitch line in lbs.; y = Lewis factor for circular pitch gears; s = Safe stress at given pitch line velocity in lbs. per sq. in.; f = Width of face in ins.; p = Circular pitch of teeth in ins.; z = Lewis factor for diametral pitch gears; F = Width of face in ins.; P = Diametral pitch.

Most practical problems consist of determining a suitable pitch of teeth to transmit a given horse-power, together with the width of face, which in order to solve the equation for any particular case, is given some value in terms of the pitch. The safe stress at the given pitch line velocity is determined either from a table, or can be calculated from the equation—

$$S_v = S_o \left(\frac{600}{600 + V}\right) \quad \text{NOTE :—SEE ADDENDUM.}$$

where,

S_v = Safe stress at pitch line velocity V ft. per min. in lbs. per sq. in.; S_o = Safe stress at zero speed in lbs. per sq. in.

The following values of S_v may be taken :—

Nickel-chrome gears, 100,000 lbs. per sq. in. ; steel castings and ordinary steel cut gears, 20,000 lbs. per sq. in. ; cast iron, 8,000 lbs. per sq. in.

If the gearing is liable to serious shock or alternations in the loading, then the values of S_v calculated from the above should be reduced accordingly.

In a practical problem the approximate pitch circle diameter is usually known, or can be fixed according to the conditions ruling.

In applying the Lewis formula to the problem of finding the pitch, we have two unknowns—(*a*) Lewis factor ; (*b*) pitch of teeth. The Lewis factor depends upon the number of teeth, as also does the pitch for a given pitch circle diameter. It is common to *assume* a number of teeth and select from a table the corresponding Lewis factor. If the number of teeth assumed is incorrect as shown by the application of the formula, then fresh values for the number of teeth have to be selected until a suitable pitch is obtained consistent with strength. The method is, therefore, one of trial and error, and requires considerable judgment and experience in order to obtain suitable results.

In order to obviate this, the formula can be written as follows :—

Let,

$$\text{Width of face } f = 3p \text{ (which agrees with average practice)};$$

then, for circular pitch gears,

$$W = 3ysp^2.$$

Also,

$$p = \frac{\pi D}{N};$$

where,

$$N = \text{number of teeth}; \quad D = \text{pitch circle diameter};$$

and,

$$W = \frac{3ys\pi^2D^2}{N^2}; \quad \frac{y}{N^2} = \frac{W}{3\pi^2D^2s}.$$

Multiplying the right-hand side of equation by 10,000, adjusting values of $\frac{y}{N^2}$ accordingly, we get

$$\frac{y}{N^2} = \frac{337{\cdot}7W}{D^2s},$$

which permits easier tabulation and facilitates reading.

For diametral pitch gears,

$$W = \frac{S.F.Z.}{P} = \frac{S.F.Z.D}{N}; \quad W = \frac{3\pi^2D^2SZ}{N^2}; \quad \frac{Z}{N^2} = \frac{W}{3\pi D^2S}.$$

Or, multiplying the right-hand side by 10,000,

$$\frac{Z}{N^2} = \frac{1061W}{D^2S}.$$

If other values for the width of face are required the formulæ become

$$\frac{y}{N^2} = \frac{1013{\cdot}2W}{KD^2S} \text{ for circular pitches,}$$

and

$$\frac{Z}{N^2} = \frac{3183W}{KD^2S} \text{ for diametral pitches.}$$

$$K = \frac{\text{width of face}}{\text{circular pitch}}, \text{ a value to be decided upon initially.}$$

If values of $\frac{y}{N^2}$ and $\frac{Z}{N^2}$ are tabulated, then it becomes unnecessary to assume the number of teeth, since this can be seen at a glance from a table when the above calculation has been made, and the required pitch of teeth can then be found for the given pitch circle diameter.

Some slight adjustments may be necessary in order to make the pitch such as to enable the gear to be cut by the usual standard cutters.

No. of Teeth.	Involute 20° Obliquity.				Involute 15° Obliquity.

150	0·146	0·459	0·0644	0·204	0·120	0·377	0·0533	0·168
300	0·150	0·472	0·0166	0·0524	0·122	0·384	0·0135	0·0426

Example.—A spur gear is required to transmit 60 h.p. from a motor shaft running at 400 revs. per min.; the gear is to be of steel, having an approximate pitch circle diameter of 8 ins. What will be the pitch of the teeth, and width of face, for 20° involute gear?

$$\text{Horse-power transmitted} = \frac{WV}{33{,}000}; \quad V = \frac{\pi \times 8 \times 400}{12};$$

therefore,

$$W = \frac{60 \times 33{,}000 \times 12}{8\pi \times 400} = 2{,}362 \text{ lbs.}; \quad S_v = 20{,}000 \left(\frac{600}{600 + 837{\cdot}5}\right) = 8{,}350 \text{ lbs. per sq. in.};$$

$$\frac{y}{N^2} = \frac{337{\cdot}7 \times 2362}{64 \times 8350} = 1{\cdot}49.$$

From the table, the value of 1·49 corresponds most nearly to 27 teeth; the face width will therefore be 2·8 ins.

The Lewis formula is based upon the assumption that the entire loading comes upon one pair of mating teeth, and that the load is concentrated at the tooth point. The compressive and shear components are ignored. The result is that the teeth so designed are somewhat on the heavy side. It should, however, be realised that teeth wear away from their original true shape, and hence the point of application of the load may reach the tooth point, and it may possibly occur that the load is borne by one pair of mating teeth at some particular instant.

Gearing on Armature Shafts.

In gearing, large revolving masses—as, for example, armatures of motors—should be separated from adjoining masses, such as large gear-wheels of the second motion, by some elastic medium, such as a length of shafting or a flexible coupling. This is intended to allow for slight variations in the angular velocity, due to unavoidable errors in cutting the teeth, to take place without giving rise to destructive loads between the teeth. The stresses due to inaccuracies in the spacing of the teeth may exceed the working stress. With an error of only 0·2 per cent. in the pitch the excess load due to acceleration and retardation may amount to as much as 28 times the load transmitted. Such loads increase as the square of the mean pitch-line velocity and as the mass of the wheel considered.

Non-Resonant Pinions.

Raw-hide, fibre, fabroil, bakelite, and other similar materials, are often used for non-resonant pinions. The pinions driving from the shafts of electric motors are frequently made of one of these materials.

The stipulation that the number of teeth in the wheel should not be an even multiple of the number of teeth in the pinion is now obsolete, if modern methods of gear cutting are employed.

For bakelite pinions the safe stress at the basic speed $S_o = 6{,}000$ lbs. per sq. in. In order to allow for pitch line velocity, the American Gear Manufacturers' Association recommend the use of the following formula, which can also be applied when either of the other materials mentioned are used, provided suitable values of S_o are adopted.

$$S_v = S_o\left(\frac{150}{200 + V} + 0{\cdot}25\right).$$

The general procedure for calculating gear strength is then as for metal gears.

Raw-hide Pinions.

Often made to replace metal pinions running at high speed. 1,600–1,700 ft. per min. is generally considered maximum pitch line speed. When power to be transmitted is high, metal reinforcing plates on the sides are required. For this purpose bronze plates bolted or riveted are common. The maximum tooth pressure per in. width of tooth face is about 250 lbs., the pressure being decreased as the pitch line velocity increases. For 1-in. pitch gears about 140–150 lbs. is usual.

It is important to keep oil and grease away from raw-hide pinions, as mineral oil proves most destructive. A dressing of raw linseed-oil occasionally keeps the material in good condition and preserves it.

Fabroil Gears.

(By permission of The British Thomson-Houston Co., Ltd.)

Fabroil as used by the B.T.H. for non-resonant gears has a distinct advantage, that it is not affected by the action of water, acid fumes, or hot or cold oil.

Gears made from this material have been used extensively for quayside and wharf machinery, on donkey-engines and various purposes aboard ship, and also in chemical works.

The material is elastic, and is thus capable of absorbing shock. For delicate machinery, where vibration would be detrimental, these gears are most useful.

Fabroil gears are made in three forms, each of which can be supplied with spur, bevel, or spiral teeth : (*a*) shrouded ; (*b*) moulded ; (*c*) without shrouds, made from sheet material or board.

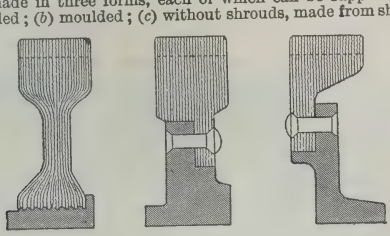

FIG. 7.

Fig. 7 shows how the fabric elements follow the contour lines of the gears, the web being obtained without machining.

The gears are cut to Brown and Sharpe's standard 14½° involute section, but other forms can be made if desired.

The wearing qualities of this material have proved excellent, and besides extending the life of the mating gear, will often outlast a metal gear working under the same conditions.

Before running these gears a light dressing of vaseline and graphite should be given, and periodically similar treatment applied.

Fabroil gears must not be used in conjunction with uncut cast-iron gear-teeth or with other teeth which are badly worn.

The strength of the teeth may be calculated by using the Lewis formula for the particular case under consideration, provided suitable constants are employed. These are as follows :—

Values of 'S' * (Unit Stress) for Fabroil Gears at Different Speeds.

The table below has been compiled from the results of recent intensive tests. The values given for 'S' at the stated pitch line velocities allow greater tooth loads to be carried at high pitchline

* These values of 'S' apply only to shrouded gears. Multiply by 0·8 for other types of gear.

velocities than is the case with cast-iron gears. This is permissible in view of the fact that the Fabroil material has much greater shock-absorbing capacity than cast iron.

Pitch Line Velocity in ft. per min.	100 or Less.	200	300	600	900	1,200	1,800	2,400
Values of 'S'	5,500	3,440	3,025	2,405	2,120	1,960	1,785	1,695

Size of Tooth.

The following table gives the diametral pitch of gearing recommended for the maximum H.P. transmitted. While smaller teeth may afford sufficient strength in some cases, these standards should be adhered to as far as possible :—

Max. H.P. Transmitted.	Diametral Pitch.	Max. H.P. Transmitted.	Diametral Pitch.	Max. H.P. Transmitted.	Diametral Pitch.
$\frac{1}{6}$	12	5	6	50	$2\frac{1}{2}$
$\frac{1}{3}$	10	$7\frac{1}{2}$	5	60	$2\frac{1}{2}$
$\frac{1}{2}$	10	10	4	75	2
$\frac{3}{4}$	10	15	3	100	2
1	8	20	3	125	$1\frac{1}{2}$
2	8	25	3	150	$1\frac{1}{2}$
3	6	—	—	—	—

The minimum number of teeth should be 18 to 20, if possible.
Gears with less than 16 teeth should never be used if it can be avoided.

Width of Face of Fabroil Gears.—The width of the non-metallic face in the case of shrouded gears should be equal to the face of the mating gear plus the aggregate end play of both shafts. The metal mating gear must not be allowed to mesh with the shrouds.

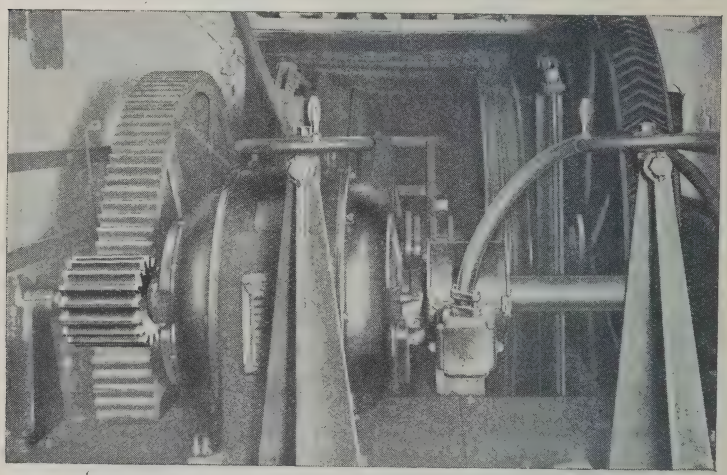

Fig. 8.—Colliery Haulage Gear with Fabroil Gear Drive.

Resilient Steel Gears.

(Seymour's Patent.)*

These gears are designed and constructed specially for drives where the strength and durability of steel gears is necessary, but where the noise accruing from their use would not be permissible.

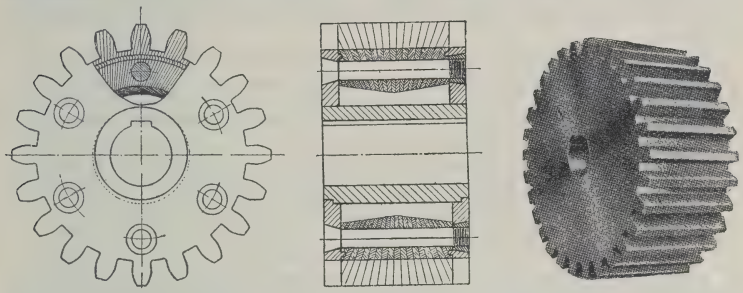

Fig. 9.—Section of Pinion with a Portion of End-plate cut away.

The portion of the gear-wheel from which the teeth are formed is made up of steel laminæ, having an ultimate tensile strength of 45 tons per sq. in., the boss and shroud plates being constructed of cast or forged steel.

The resilience of the working surfaces of the teeth afforded by this method of construction is sufficient to render the running of the gears as noiseless (even when the same are considerably overloaded) as gears constructed of raw hide, paper, and woven fabrics.

On account of the superior strength and durability of steel over the other substances named, the resilient steel gears transmit many times the load for any given size of tooth, and their life is longer proportionally.

Owing to the internal system of automatic lubrication, only the necessary amount of lubricant is supplied to the surfaces of the teeth, thus preventing waste and effecting a saving of $3\frac{1}{2}$ to 4 per cent. of the power transmitted.

Important improvements in the construction of these gears have been made, notably the connecting together of the lateral extremities of the laminæ by welding, thus the laminæ are firmly secured together independently of the support supplied by the shroud plates and bolts.

These gears have been successfully applied to almost every class of drive, including mine and quarry machinery and haulage, electric motor drives, pumps, air compressors, machine tools, cranes, etc., etc.

Fig. 9 shows laminæ and shroud plates held together with bolts.

The cavity between the boss and the laminæ is the receptacle for the lubricant; centrifugal force propels the lubricant radially outwards between the laminæ, thus efficiently lubricating the entire working surface of the teeth.

The power transmitted by such gears can be calculated from the following formula :—

$$F = \frac{HP \times 1000}{K \times N \times R'}$$

where,

F = Face width of pinion in inches; N = No. of teeth; K = Factor for each pitch (see table); R = Revolutions of pinion per minute; HP = Horse-power to be transmitted.

Circular Pitch . .	$\frac{1}{2}''$	$\frac{5}{8}''$	$\frac{3}{4}''$	$\frac{7}{8}''$	$1''$	$1\frac{1}{4}''$	$1\frac{1}{2}''$	$1\frac{3}{4}''$	$2''$	$2\frac{1}{4}''$	$2\frac{1}{2}''$	$3''$
Factor K . . .	·225	·35	·505	·689	·9	1·41	2·03	2·75	3·6	4·55	5·63	8·1

Factor K . . .	·246	·355	·555	·723	·975	1·41	1·74	2·22	2·92	3·93	5·67	8·9

* The Skerne Works, Ltd., Darlington, informs us that they no longer make this gear but produce the Skerne Resilient Gear instead.

Gearing Noises.

During the last few years considerable attention has been given to noise produced by gears. The kind of noise produced by a pair of gears will often give some indication of defects present.

High-class gearing running in perfect order produces a low-pitched humming sound with absence of beats, the sound being quite 'smooth' and continuous.

The greater the accuracy in machining the teeth and the better-class finish put upon the tooth faces, all tend to reduce noise. Irregular spacing of teeth is a common defect, and can be recognised by an intermittent clicking or a pulsating howl. Similar sounds occur when teeth are mis-shaped.

A pulsating howl may also arise due to improper setting of the gears upon their spindles. Eccentricity is a common cause.

High-pitched screeching often occurs, due to rough tooth faces. A common defect, particularly in heavy gearing, is to use either too little support for the shafts or too small a shaft diameter. Such errors set up spring in the shafts, resulting in pulsating sounds of varying pitches according to the pitch-line velocities.

A good condition of a set of gears, particularly those running at high speed, is indicated by a more or less musical sound, or sounds of constant pitch.

In the case of gears which are required to run in either direction, the fact that noise prevails more in one direction than another indicates that the teeth are not radial.

Generally, fine-pitched teeth and wide face widths tend toward noise reduction.

Critical Speeds* of Gearing.

Certain conditions of gear-teeth surfaces after running for some time cannot be directly traceable to general causes. Results of investigations go to show that the running of gear shafts at speeds too near that of the critical speeds results in the development of rough tooth profiles and general deformation of the surfaces in contact. Vibrations are often manifest in gearing, particularly in the case of high speeds. These will be considerably increased if they harmonise with those of the shaft at its critical speed, and such conditions may produce fracture.

In cases where gears are running at or near the critical speeds of their shafts, unsatisfactory running will invariably result. Hence dimensions of shafts must be arranged so that this defect is avoided.

Approximate rule for determining critical speed :—

$$S_c = \frac{188}{\sqrt{\delta}}$$

where,

S_c = critical speed of shaft in r.p.m.; δ = max. deflection of shaft in ins.

If a gear is required to run above the first critical speed, then when starting up the gear must be allowed to pass quickly over this critical speed period. In general, the working speed of a gear should not be within 28 per cent. or 30 per cent. of the critical speed.

Grinding of Gear Teeth.

The necessity of running gears at high pitch line velocities up to 16,000 or 17,000 ft. per minute has given rise to the need for finer and more accurate finishing of tooth profiles. Hardened steel gears used under severe conditions are ground. At high pitch line velocities small defects in the tooth faces are very detrimental to efficient and continuous working.

Defects in tooth faces produce noise, and may also reduce the safe load that can be transmitted by a tooth.

As compared with cut gears, those which are ground produce a characteristic high-pitched note when running under load and at high pitch line velocity. Even fine cut grinding-wheels do not produce a sufficiently smooth surface to entirely eliminate noise, but after ground gears have been in service for a short time they should, if accurately cut, run almost noiselessly.

When gears are to be ground, errors due to the wearing of the grinding-wheel must be guarded against. The material from which the abrasive wheel is made must be carefully selected. No specific recommendation can be given as details affect each particular case, as does the material to be ground. Neither very hard nor very soft wheels should be employed. To secure most accurate results and hence guard against wear of wheel, precaution should be taken when grinding gears. A suitable dividing head should be employed, and arrangements made so that the first and last teeth to be ground are not adjacent. Such an arrangement reduces error due to wear of abrasive wheel. Care should be taken to grind teeth in such a way that the error is evenly distributed.

Lapping Gear Teeth.

The idea of running hardened gears together with lubricant and abrasive material has been tried. For producing a highly finished surface to the tooth faces the method is not satisfactory,

* See Morley's 'Strength of Materials' for complete treatment.

but it serves to correct slight errors in tooth profiles. From a production point of view the method is not satisfactory.

Good results as regards finish and accuracy can be obtained by running a hard steel gear in mesh with one made of softer material and having a wide face. Both gears should be run at high speed and with load on while abrasive material and lubricant are applied to the tooth faces. The hard gear should be made to traverse the face of the wider soft gear.

In some cases cut gears are run with load on with two or three hardened and ground gears. This process tends to produce a well-burnished tooth surface.

Hardening of Gears.

Appreciable wear on gear teeth rapidly causes deterioration of the tooth faces, with consequent serious results. Hence some method of hardening is required, particularly in cases where the working conditions are severe, as is the case of those for automobile drives. Such gears are invariably hardened.

Processes vary greatly, and great care is needed to prevent serious warping. To preserve accuracy slow and uniform heating is essential. Such treatment also tends to produce a homogeneous metal as a result. After preheating the chemical treatment is applied to the skin until a condition is secured suitable for the final quenching. The quench, which is usually made in an oil bath, should be so carried out as to ensure rapid and even cooling.

A successful process of hardening automobile gears is given by the *American Machinist*. It is claimed that a minimum amount of warping occurs, and the shrinkage of the shaft holes is inappreciable. The average case thickness is approximately 25 thousandths of an inch.

The gears are preheated in a large gas-oven or forge until a dull red heat is obtained; temp. about 1300°–1900° F. The gears are then boiled in a solution of cyanide of potassium for about 1 hr. After this treatment the gears are plunged into a bath of fish oil which is kept constantly in circulation to ensure uniform temperature throughout.

Heat Treatment of Gears for Machine Tools.

The use of case-hardened gears for this, and many other purposes, is to a large extent being superseded by the use of high carbon steel treated so as to give uniform texture throughout the gear tooth section. Although gears so treated do not appear to be so hard as when case-hardened, yet when put into service they wear well and retain their shape and size for a very long time.

Straight carbon, nickel, chrome-vanadium, and chrome-nickel steels are used for gears which are intended for case carbonising. Other similar alloys are also obtainable for the same purpose.

Generally speaking, a chrome alloy steel is to be recommended in preference to a nickel one for gear manufacture, since lamination is less likely than with nickel steel, particularly the 3½ per cent. variety.

For case-hardening purposes the carbon should be about 0·2 per cent. The carbon in case should be changed by the use of carbonising material, and working at correct temperature, to about 0·9 per cent. Temperature of carbonisation for the steels mentioned should be about 1600°–1650° F.

The final treatment by heat after the casing is particularly important, as both the core and the case need bringing to the proper state in order to secure full advantage of the hardening process.

Treatment.

The gears should be reheated, after having been cooled off when carbonised, to about 1600° F. and quenched. This produces the required core texture. To harden the case again reheat to about 1400°–1425° F. and quench. To provide additional toughness the gear may then be drawn through an oil bath at a temperature of 425° F.

High Carbon Gears.

The advantages of alloys in this category have been referred to. In addition gears made from these alloys, and heat-treated in proper manner, are less liable to serious distortion by warping, and are stronger. The process of hardening is generally of a simpler character and probably cheaper, although material may be slightly more expensive.

Chrome-nickel alloy is the chief material used for gears intended to be hardened throughout. Chrome-vanadium steel is also used.

Before heat treating, the correct temperatures to be used in the processes should be obtained from the steel makers. Generally the temperature should be raised gradually to about 1500°–1550° F., and then quenched in an oil bath. Further treatment consists of drawing through an oil bath after the first quenching. Such treatment, as given above, is applied to automobile gears and to other gearing working under equally severe conditions.

In all cases where gears have to be hardened the chief difficulty to contend with is warping, and hence in gearing design, sudden changes of section should be avoided; under-cutting at the tooth roots is also liable to give trouble and should not be resorted to when gears have to be hardened.

Bevel Gears.

In the case of bevel gears the diameter understood is the diameter of the base of the pitch cone D, fig. 10. The pitch is measured on this circle. In fig. 10, A and B are a bevel pair revolving on shafts OM and MN. AM represents the pitch cone surface of A and B. OA and EK are drawn at right angles to AM to cut the axes at O, H, and KL respectively. AH and AO are then

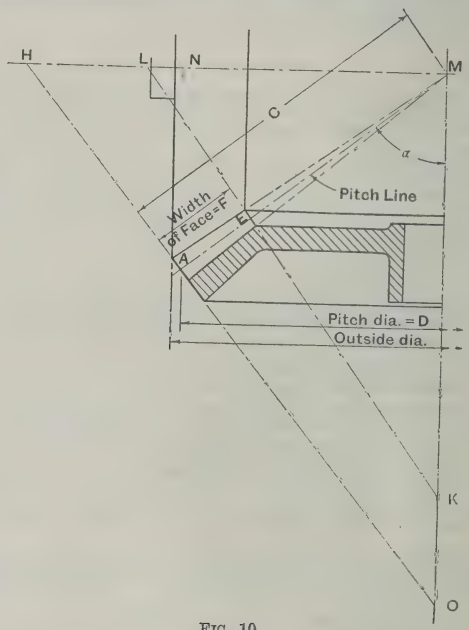

FIG. 10.

the virtual radii of the wheels A and B, and represent the radii of two spur gears which will gear similarly to the bevel pair. These are used as base-lines for setting out the teeth of the bevels A and B. Similarly, EL and EK are the radii for setting out the inner ends of the bevel teeth. The complete tooth lies evenly between these two shapes thus produced.

N' = no. of teeth in the equivalent spur gear; α = pitch cone angle.

$$N' = \frac{\text{No. of teeth in bevel gear.}}{\cos \alpha}.$$

Mitre Wheels.

If two shafts are at right angles and are connected by a bevel pair whose diameters are equal, giving equal speed of rotation, then such wheels are called *mitre wheels*.

Strength of Bevel Gears.

With slight modification the Lewis formula can be applied to bevel gears.

The modified form for bevel gears is—

$$W = \frac{Y s F(C - F)}{PC},$$

where,

P = diametral pitch; Y = Lewis factor selected from the table (p. 925); C and F are the dimensions given in fig. 10.

The factor $\frac{(C - F)}{C}$ approximately expresses the ratio of strength of a bevel gear to that of

a spur gear having the same number of teeth and pitch. As the pitch changes in a bevel gear the strength varies and hence the use of the modifying factor.

EXAMPLE.—Determine the maximum safe load that can be carried by a cast-iron bevel gear 3*d.p.* 20 ins. diameter. Pitch cone angle 76°, speed of wheel, 75 r.p.m.; angle of obliquity, 20°; width of face, 4 ins. Calculate also the safe horse-power that could be transmitted.

$$\text{No. of teeth in bevel gear} = 3 \times 20 = 60.$$

$$\text{Pitch-line velocity} = \frac{3{\cdot}1416 \times 20 \times 75}{12} = 400 \text{ ft. per min.}$$

$$N' = \frac{60}{\cos 76^\circ} = 250 \text{ teeth}; \quad S_v = S_o\left(\frac{600}{600 + V}\right) = \frac{8{,}000 \times 600}{1{,}000} = 4{,}800 \text{ lbs. per sq. in.}$$

$$C = \frac{10}{\sin. 76^\circ} = 10{\cdot}3 \text{ ins.};$$

$$W = \frac{Y S F(C - F)}{PC} = \frac{0{\cdot}467 \times 4{,}800 \times 4(10{\cdot}3 - 4)}{3 \times 10{\cdot}3} = 1{,}830 \text{ lbs.}$$

$$\text{Max. safe horse-power} = \frac{1{,}830 \times 400}{33{,}000} = 22.$$

VALUES OF 'Y' FOR BEVEL GEARS.

Maag Gearing.

This type of gearing introduces certain novel features both in production and shape of tooth profile. It is claimed that the full benefit of the involute tooth profile can be obtained with this

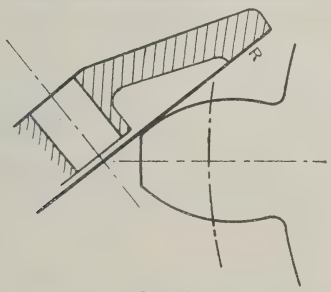

FIG. 11.

form of gearing. Standard tooth form is not adhered to, the teeth being cut on the generating principle and a true involute profile for each gear tooth obtained. Any pitch can be cut, using the same standard tool, which is in the form of a straight-sided rack cutter; i.e. the teeth are formed by cutters whose shapes correspond to the shape of the rack belonging to the gear wheel.

One of the essential features of this type of gearing is in the hardening and grinding of the teeth. The case is hardened to a depth of approximately ·04 in., after which it is drawn to a temperature of 200°–300° F. and ground.

The highest possible degree of precision is obtained in this grinding process, carried out on special machines having specially shaped abrasive wheels, which are accurately mounted and tested for wear by special means. The generating principle is used in this operation as in the milling operation.

Two abrasive wheels are inclined to each other so as to form by their lateral surfaces the tooth profile of the rack to which the gear belongs. The surfaces of the abrasive wheels are made hollow, so that the part marked R (fig. 11) only, forms the working plane.

Despite wear, this projecting part describes a working plane at right angles to the axis of rotation of the shaft.

Against this grinding form the gear is rotated in the correct way to give the proper shape of tooth—that is, it rolls with its pitch circle on a line corresponding to that of the rack.

The grinding wheels are moved backward and forward, so as to completely traverse the whole face width of the gear. The gear is also rolled until grinding is complete across the whole tooth face.

To allow for the wear of the abrasive wheels, compensation is provided by way of an automatic electrical device which keeps the planes of the grinding wheels in their exact position.

It is claimed that much higher tooth load can be carried by Maag gears at higher pitch-line velocities than with other types of gearing. It is further claimed that pitch-line speeds of 10,000 ft. per minute to 15,000 ft. per minute are possible, while the load per inch width can be double that allowed with double helical gears.

In the Swiss 2,500 h.p. locomotives, Maag gearing was used in place of the double helical gearing.

The increase in load-carrying capacity of Maag teeth is accounted for by the fact that the teeth are thicker at the root than ordinarily cut gears.

DEVICE FOR ADJUSTING ABRASIVE WHEELS FOR WEAR.

(German Patent No. 303014.)

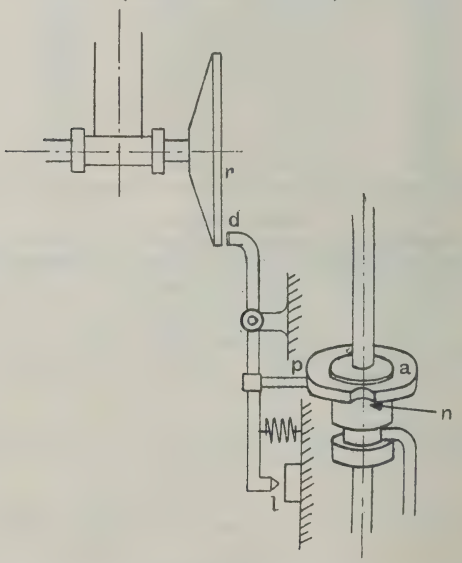

FIG. 12.

Fig. 12 shows the mechanism. *d* is a diamond contact piece which at uniform time intervals, controlled by the rotating disc *a*, is brought into contact very gently with the rim *r* of the abrasive wheel. The disc *a* has a notch *n* in its rim, into which the projecting piece *p* drops; thus the contact of *d* with *r* is at equal time intervals as *a* rotates uniformly.

If the abrasive wheel has worn, then the diamond piece follows it and brings an electrical contact l into action, which operates a mechanism to bring the abrasive wheels into their correct position. The electric contact breaks as soon as the adjustment is complete.

In order to check the accuracy of tooth profile a special machine is used. (*Saurer Arbur.*)

HELICAL GEARING.

Spiral or helical gears are used to transmit motion between two non-intersecting shafts, the axes of which may be inclined to one another at angles varying between 0° and 90°. When the shafts are at 90° to one another the drive is similar to that of a worm and worm wheel. Although the term 'spiral' is often used to indicate this type of gearing, actually each tooth is part of a helix, and the correct description of such gearing is helical rather than spiral.

Definitions.

'*Normal circular pitch*' is the distance between the centres of two consecutive teeth measured round the pitch cylinder and at right angles to the tooth.

'*Circumferential or real circular pitch*' is the distance between the centres of two consecutive teeth measured round the pitch cylinder and in a plane perpendicular to the axis of rotation. See fig. 13.

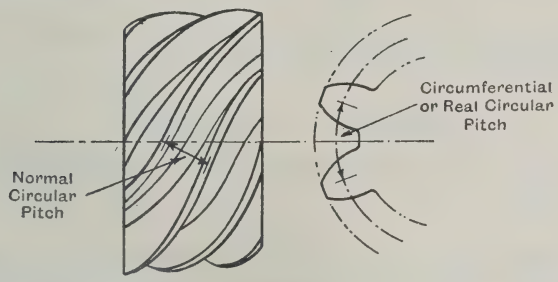

FIG. 13.

'*Spiral angle* (θ).'—The angle which the tooth helix makes with the axis of rotation. Fig. 14.

'*Lead angle* (λ).'—The complement of the spiral angle, or the angle between the tooth helix and a plane perpendicular to the axis of rotation. Fig. 14.

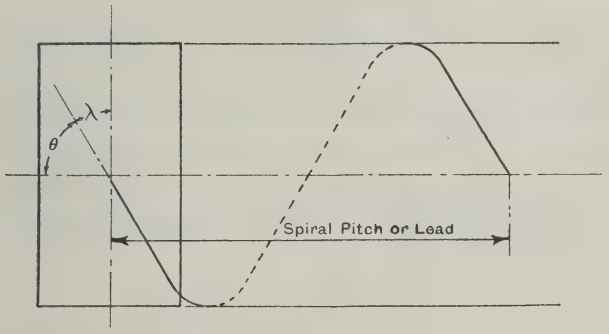

FIG. 14.

'*Spiral pitch or lead.*'—A spiral gear can be considered as a portion of a multiple-threaded screw. If the gear was made wide enough each tooth would make a complete turn on the blank.

The angle of the teeth controls the pitch of this complete turn, known as the *spiral pitch or lead.* In order to cut the teeth at any desired angle the lead is required. See fig. 14.

$$\text{Lead} = \frac{\text{Pitch circumference}}{\text{Tan } \theta}, \text{ where } \theta = \text{spiral angle.}$$

Increase of spiral angle increases the circular pitch, and hence the pitch diameter for the same number of teeth.

'*Normal pressure angle*' is the angle between a tangent to the tooth profile at the pitch cylinder and a radial, the angle being measured normal to the spiral. Definitions given previously for pitch cylinder, pitch diameter, etc., are similarly applied to spiral gears.

θ = spiral angle *r.c.p.* = real circular pitch ; *n.c.p.* = normal circular pitch ;

N = no. of teeth ; *r.d.p.* = real diametral pitch ; *n.d.p.* = normal diametral pitch ;

$$\text{Normal circular pitch} = \text{real circular pitch} \times \cos \theta.$$

$$n.c.p. = \frac{\pi}{n.d.p.}; \quad r.c.p. = \frac{n.c.p.}{\cos \theta}$$

$$\text{Pitch dia.} = \frac{r.c.p. \times N}{\pi} = \frac{N}{r.d.p.}; \quad \text{Outside dia.} = \text{Pitch dia.} + 2\,(\cdot 3183\ n.c.p.);$$

$$r.d.p. = n.d.p. \times \cos \theta.$$

The most common example of a spiral drive is that in which two spirals are used to transmit motion between two shafts at right angles to each other.

Consider two gears A and B meshing under the conditions above.

Let

D = pitch dia. of A ; d = pitch dia. of B.
N = no. of revs. of A ; n = no. of revs. of B.
α = spiral angle of A ; β = spiral angle of B.

Velocity ratio $= \frac{N}{n}$. The number of revolutions of the wheels is inversely proportional to the numbers of teeth.

$$\text{Number of teeth in A} = r.d.p._{A} \times D; \quad \text{Number of teeth in B} = r.d.p._{B} \times d.$$

Also,

$$\text{Number of teeth in A} = n.d.p._{A} \times \cos \alpha \times D; \quad \text{Number of teeth in B} = n.d.p._{B} \times \cos \beta \times d.$$

Since the wheels are in mesh the normal pitches must be the same, hence $n.d.p._{A} = n.d.p._{B}$.

Therefore,

$$\frac{\text{No. of teeth in A}}{\text{No. of teeth in B}} = \frac{D \cos \alpha}{d \cos \beta}$$

$$\frac{N}{n} = \frac{d \cdot \cos \beta}{D \cdot \cos \alpha} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

and since $\alpha = 90 - \beta$, and $\cos \beta = \sin \alpha$, therefore

$$\frac{N}{n} = \frac{d}{D} \tan \alpha \quad . \quad . \quad . \quad . \quad . \quad (2)$$

The above relations are true for right- or left-handed spirals, and hold good for any two wheels in mesh, whether axes are at right angles or not. The only difference will be in the relation between α and β.

From equation (2) the required spiral angles can be obtained for a given velocity ratio and given diameters.

EXAMPLE.—The camshaft for a 4-stroke cycle gas-engine is to be driven by a right-angled spiral drive. Determine the spiral angles of the two gears.

The gear diameters are usually equal in cases of this sort. The speed reduction is 2 to 1, the camshaft running at half engine speed.

$$\frac{N}{n} = 2 = \frac{d}{D} \tan \alpha. \quad \frac{d}{D} = 1,$$

therefore,

$$\tan \alpha = 2.$$

Hence,

$$\alpha = 63° 26', \text{ and } \beta = 26° 34'.$$

When the spiral angles have been calculated, the actual diameters must be obtained, so that with a standard normal pitch an integral number of teeth is given.

In the case of single helical drives the provision of some means to take up end-thrust is essential. Ball thrust bearings are commonly used, while for light duty a plain collar on the shaft, bearing against a bronze bush or end-pad is satisfactory.

Let

H.P. = horse-power transmitted by a pair of gears; V = pitch line velocity in ft. per min.; P = tangential load on the teeth; $\text{H.P.} = \frac{\text{PV}}{33{,}000}$; $\text{P} = \frac{33{,}000\ \text{H.P.}}{\text{V}}$

If P_a = axial thrust, then $\text{P}_a = \text{P} \tan \theta$.

'Tooth face width.'—This should not be less than about $2\frac{1}{2}$ to 3 times the normal circular pitch, to ensure proper continuity of action. The normal tooth profile is involute.

The cutter for milling spiral gears is not selected according to the number of teeth as is the case with spur gears. The number of teeth in the spiral gear is divided by the cosine of the spiral angle cubed, i.e. $\frac{\text{N}}{\cos^3 \theta}$. When this calculation has been made, the resulting number is the number of teeth for which the cutter is selected.

Addendum $= \frac{1}{n.d.p.}$; Whole depth of tooth $= \frac{2 \cdot 157}{n.d.p.}$; Normal tooth thickness at pitch line $= \frac{1 \cdot 571}{n.d.p.}$.

Double Helical Gears, or Herring-bone Gears.

When accurately designed and well made this type of gearing has many advantages compared with other forms of gearing. The chief advantages are:—

(*a*) The engagement of the teeth is continuous when proper face width is used, and hence greater loads can be transmitted with high degree of efficiency.

(*b*) Vibration is practically eliminated.

(*c*) Shock is eliminated as the teeth are in continuous engagement, hence the load is transferred from tooth to tooth smoothly. Wear is thereby reduced, and also noise.

Tooth Profiles.

The normal tooth profile used is the involute. Pressure angles of 20° are used by most manufacturers. In some cases the $14\frac{1}{2}$° angle has been adopted, while for special cases other angles have been employed.

Spiral angles.—In the case of staggered teeth the angle adopted is usually 23°. For fine pitched turbine gears 30° is common, while for winding machinery, haulage purposes, etc., 45° is often used.

Face Width.

The total face width should not be less than 5 times the normal circular pitch. High ratio gears have face widths up to 12 times the normal circular pitch.

Tooth Proportions.

There does not appear to be any standard tooth proportions. The following are, however, values conforming to average practice:—

Staggered teeth, 23° pressure angle, addendum $= \frac{\cdot 8}{dp}$; dedendum $= \frac{\cdot 96}{dp}$.

Continuous teeth, 45° angle. Addendum $= \frac{\cdot 7}{dp}$; dedendum $= \frac{\cdot 85}{dp}$.

Strength of Double Helical Gearing.

Proportions of Teeth.

Thickness of tooth $= \frac{cp}{2}$; Addendum $= \frac{\cdot 89 \times cp}{\pi}$; Dedendum $= \frac{1 \cdot 05 \times cp}{\pi}$.

cp = circular pitch.

In the case of helical gears with continuous teeth, the formulæ vary according to the kind of machinery for which the gears are intended, and they are very numerous.

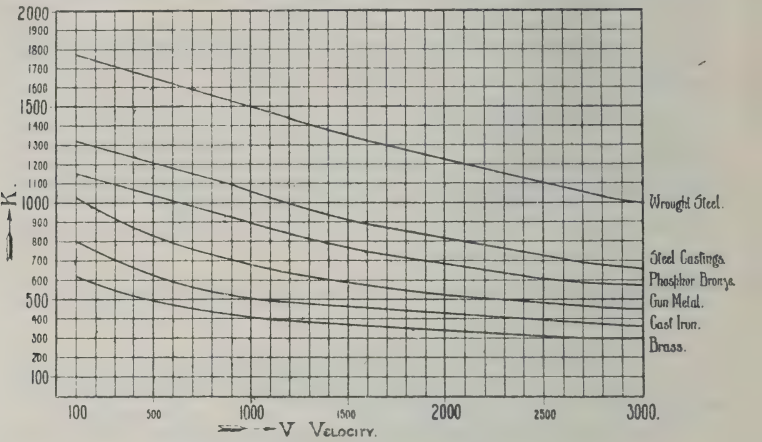

FIG. 15.

MOUNTING OF DOUBLE HELICAL GEARS.

It is of first importance that the axes of rotation of a double helical gear reduction should be *parallel and in the same plane.* Uneven load distribution will result if this is not so. It is important that the centre distance be such that the requisite amount of back-lash is obtained. Back-lash must not be excessive, but must be sufficient to ensure proper lubrication. In special cases, such as in gun-sights, back-lash is undesirable. Excessive back-lash is liable to create hammer-blow. Back-lash may be from 5 to 10 thousandths of an inch per inch of circular pitch. The tooth thickness of both gears is reduced by half of the amount given. In high-speed gears lubricated by spraying, the gears having fine pitches, greater back-lash is often desirable.

In order to ensure that there shall be no end thrust, it is necessary for the gears to take up a position of equilibrium, and hence flexible couplings between shafts should be used.

LUBRICATION.

Low-speed gears are often lubricated by allowing the wheel to dip in an oil bath. Violent churning of the oil should be avoided, and hence this form of lubrication must not be adopted for high-speed gears. For this latter purpose sprayers are used, the oil being supplied by a pump.

Triple Helical Gears.

A gear having two changes in the hand of the helices is called a triple helical gear. Such gears are sometimes used in mining machinery. The idea of the triple helical gear apparently evolved from the notion that helical gears gave best results when the apex of the teeth pointed in the direction of rotation, and hence the triple gear provided the best form of gear for reversing. Such a contention does not, however, appear to have much to support it in the light of modern gear technology. They are, however, still in some demand, and engineers occasionally specify them.

TURBINE GEARS.

The fact that large horse-powers are transmitted at high pitch-line velocities calls for special consideration in manufacture. Pitch-line velocities up to 18,000 ft. per minute are dealt with. Speed reductions from turbine shafts to electric generator shafts, mill shafts, and ships' propeller shafts need specially designed and accurately made gearing. Similar kind of gearing is needed to increase speed from internal combustion engines, electric motors, etc., required to work blowers, compressors, rotary pumps, and the like.

The arrangement of a gear reduction may be considered from three points of view :—(*a*) a single or double reduction. The limit for single reduction is 1 to 20, and in some exceptional cases 1 : 26, whilst 1 : 50 ratio has been obtained by double reduction; (*b*) turbines may be in 1 to 3 casings; (*c*) by the use of double helical (herring-bone) gears the axial thrust on the shaft is balanced automatically. Plain helical gears, if used, may be arranged to operate so that the axial thrust due to propeller or turbine rotor is balanced. The double helical gear is the more usual.

Turbine gears of the double helical type have been produced having efficiencies of 98 per cent. and 99 per cent., whilst it is common to find efficiencies of 94 per cent. to 96 per cent.

Wear on Teeth.—When running at high efficiency the wear is small—in fact, helical gears running with high-speed machines, such as the De Laval turbine, have been known to show little or no wear after several years of service. Such results can only be expected when materials and manufacture are of the best, as well as with careful use.

Uneven stresses setting up pitting of gear teeth and large amount of wear may occur on marine installations, due to rough weather causing straining in the larger gear wheels.

Turbine Gear Arrangements.

Figs. 16 to 23 show diagrammatically different turbine gear arrangements as follows :—

Fig. 16.—Single casing turbine with single reduction gear.
Fig. 17.—Twin turbine casings, single reduction.
Fig. 18.—Three turbine casings, single reduction.
Fig. 19.—Four turbine casings in groups.

To allow the condenser to be placed below turbine the L.P. casings are arranged so that the pinions mesh near the top of the wheel, as in figs. 22 and 23.

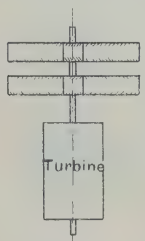

FIG. 16.

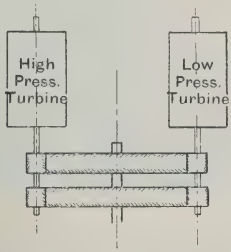

FIG. 17.

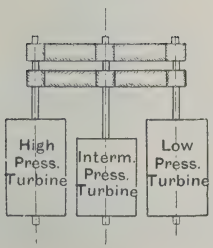

FIG. 18.

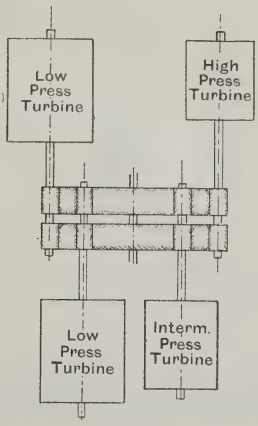

FIG. 19.

Fig. 20 shows a twin turbine double reduction.

Fig. 21 shows an arrangement for securing a more symmetrical stressing of pinions and reduction in twist than with the previous arrangement. The intermediate gears are arranged in the centre of the divided main gears.

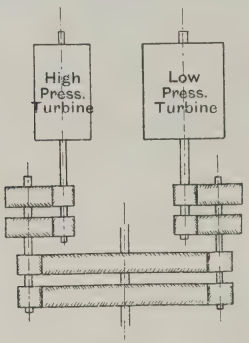

FIG. 20.

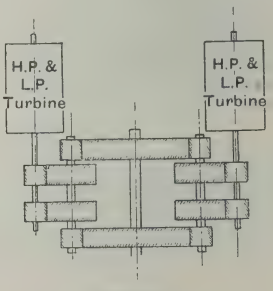

FIG. 21.

Fig. 22 shows single helical gear reduction by Messrs. Brown, Boveri et Cie.*

Fig. 23 shows Messrs. Parsons' gear reduction arrangement.

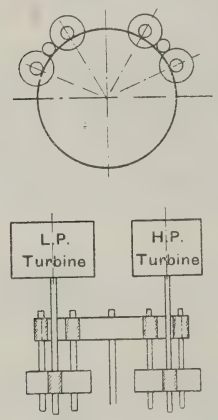

FIG. 22.

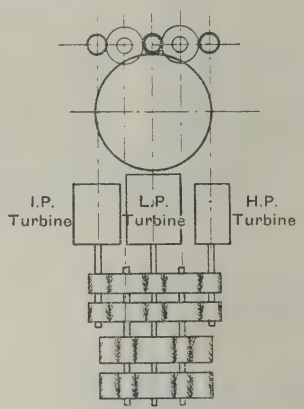

FIG. 23.

One of the factors to be taken into account when deciding upon the tooth pressure is the danger of the oil film failing if this pressure is too high. According to H. M. Martin (*Engineering*, August 11, 1916), the stress on the oil film obeys some such law as $p = bdn$, where

* Nozzles 0·10 in. to 0·15 in. diameter are employed, spaced 1½ ins. to 4 ins. apart. Oil pressure is governed so that the rate of flow is about ·33 to ·67 gals. per minute per inch width of tooth when peripheral speed is 33 ft. per second. When peripheral speed reaches 130 ft. per second, 1·0 to 1·32 gals. per minute per inch width are used. Nozzles having too small a bore should not be used, since clogging is liable to occur. It is a further advantage to have the oil reservoir above the level of the gear wheels. Too high a jet velocity should not be used as atomisation of the oil is likely.

p = load on tooth per inch run in lbs.; d = pitch diameter of pinions in inches; and b = constant; n is given as $\frac{1}{4}$, and b is taken by Messrs. Parsons as 175, but values of 250 have been used.

In most of the examples given the pinions are located above the gear wheels with which they engage. The pinions are divided, each pinion or wheel forming one-half of the double helical gear.

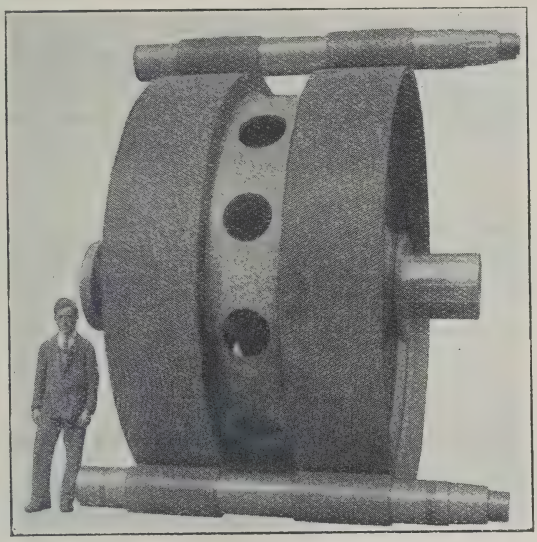

FIG. 24.

An example of a modern single reduction turbine gear made by the Power Plant Co. of West Drayton is shown in fig. 24. Each wheel transmits 35,000 h.p., the speed reduction being 2,880/288 r.p.m.

The figure shows gears of the type which have been fitted to the French cruisers *Duquesne* and *Tourville*.

Turbine Gear-Tooth Design.

An important factor in tooth design is the limiting pressure which can be allowed on the teeth. Points to be considered in fixing the pressure are wear, type of lubrication, and peripheral speed.

Gears for cargo steamers limiting pressure per inch width, 350 to 450 lbs., calculated on the length projected on to the shaft. In naval turbines pressures up to 850 lbs. per in. are used.

Double reduction gears tooth pressure is limited on the first pinion on account of high peripheral speed. About 450 lbs. is allowed on the first pinion, and 650 lbs. to 850 lbs. on the second.*

Considering the bending stress on the teeth due to normal tooth pressure, and assuming it to act at the tooth tips, 5,700 lbs./sq. in. to 7,100 lbs./sq. in. for cargo steamers, and 14,200 lbs./sq. in. for naval vessels, are common values.

The height of the teeth is usually about 0·6 times the circular pitch. The teeth are inclined usually at 30°.

Pitches vary. For small gears, values of $\cdot 12\pi$ to $\cdot 16\pi$ are used, while in the slower running gears, pitches of $\cdot 32\pi$ are used.

---

* Landahn has used tooth pressures up to 1,450 lbs. per in. width on gears running at 164 ft. per second and transmitting 10,000 h.p.—*Techn. Rundschau d. Berl. Tageblatt*, May 1919.

Thickness of tooth at pitch line is usually about $\frac{1}{2}$ circular pitch. Tooth clearance to allow for heating of gears and to ensure proper lubrication is usually ·01 in. to ·02 in. The centre distance is usually increased by this amount to provide clearance.

In order to secure best results the highest degree of accuracy is needed in the manufacture of turbine gears, together with accurate lining up and careful attention while at work.

The teeth are usually cut by special relief ground hobs. The end-mill process is an older method, but is still used where hobbing process is inapplicable.

For turbine gears a 20° pressure angle is used, the normal tooth profile being involute.

The fact that several teeth are in mesh, or partly so, is not taken into account, the whole load being assumed to be carried by one tooth.

The actual length of tooth carrying the load depends upon the deformation, due to bending and twisting. The amount allowed is limited to about ·0008 in. or ·0012 in.

Pinions.

Pinions are usually forged solid with shaft, and 3 to 5 per cent. nickel steel alloy is used; also nickel-chrome alloy in some cases. The number of teeth is not often less than 30 or 35. For cargo steamers and the first reduction gear, pitch-line velocities of 80 ft. per second are employed. For second reduction gear, 28 to 40 ft. per second are used, while naval gears run at 150 ft. per second. Greater pitch-line velocities are sometimes used.

$$\text{Tooth length} = \frac{\text{tangential load on teeth}}{\text{bearing pressure per inch width}}.$$

Wheel Construction.

The wheel body is usually cast iron, having a forged steel rim shrunk on. Some makers have used cast steel entirely.

The Power Plant Co., Ltd., of West Drayton use, for the pinions, alloyed steels (nickel or chrome-nickel steel), and for the wheels above velocities of 3,000 ft. per min., forged steel rims.

The calculation must start from the requisite pinion diameter to transmit a given load without exceeding the very narrow limits within which bending and twisting are allowed.

With gears where the pinion active face exceeds three times the pitch diameter, three bearings are invariably required for the pinion, to resist bending. The slightest inaccuracies in pitching and setting of the wheels, and comparatively small bending and twisting strains are liable to affect turbine gears very adversely, but these effects can be counteracted by special designs, such as the wheels with the pressure compensating device as manufactured by the above company.

Lubrication.

In the case of gears running at high pitch-line velocities, special precautions are necessary to ensure ample oil supply between the teeth. The oil is projected on the approaching side of the gears on to a point just before meshing occurs.

Pitch.

Fine pitches give silent running at high speeds, and a normal pitch, that is, the pitch measured at right angles to the teeth, of 0·583 in. (or $\frac{7}{12}$ in.) has been largely used in this country. For small pinions, or where extreme silence is of importance, 0·4 in. in pitch has been used. For turbine gears the pitch for a pinion having at least thirty teeth may be found from the expression:

$$p = \frac{P}{WK},$$

where,

p = pitch in inches; P = total tooth load in lbs.; W = width in inches; K = constant corresponding to the velocity. (See fig. 25.)

The expression applies to teeth with normal addendum and dedendum.

The materials in turbine gearing are never highly stressed; gears are designed primarily for wear, and this gives a much greater factor of safety than would be employed were they to be designed for considerations of strength alone.

An ample supply of oil is imperative, not only to lubricate the teeth, but also to carry off the heat generated. For this purpose it is usual to have ¼ in. to $\frac{3}{16}$ in. nozzles of about 5 ins. pitch squirting oil under a pressure of 10 to 20 lbs. per sq. in. on to the pinion, some distance in

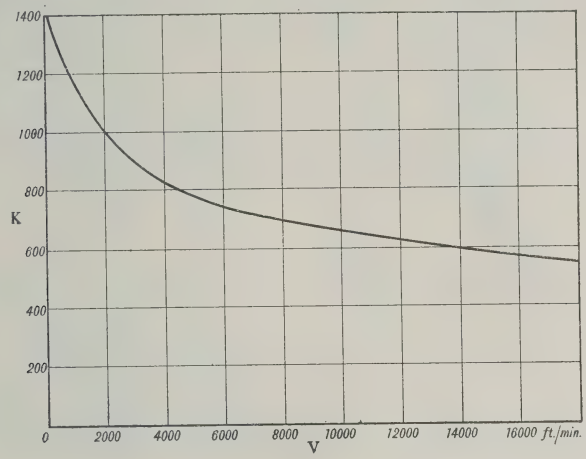

FIG. 25.

advance of the engagement, as this allows some of the oil to disperse and it is not carried forward and pumped out by the gears themselves. The quantity of oil is about 1 gal. per minute per 100 to 150 h.p. transmitted. The case must be well drained, otherwise if the wheel dips into the oil at the bottom much heat will be generated by the churning of the oil.

PINION DISTORTION.*

The distortion of the pinion is made up of two items—the twist due to the torque transmitted and the bending due to the load on the teeth. The load on the tooth is assumed to be uniform, and the effective diameter of the pinion is the pitch diameter.

At any point x in fig. 26, the torque T is :—

$$\frac{pxd}{2} = \frac{2fI}{d} = \frac{\pi f d^3}{16}$$

where f is the shear stress at the circumference of the pinion, and I is the polar moment of inertia or $\frac{\pi d^4}{32}$. Hence it follows that $f = \frac{8px}{\pi d^3}$. If N is the modulus of rigidity, which for steel is 12,000,000 lbs. per sq. in. :—

$$\frac{dy}{dx} = \frac{f}{N} = \frac{8px}{\pi N d^3}$$

$$y = \frac{4p}{\pi N} \cdot \frac{x^2}{d^3}$$

which is a parabola. The twist in the first half of the pinion is :—

$$y_1 = \frac{p}{\pi N} \cdot \frac{l^2}{d^2}$$

and in the second half :—

$$y_2 = \frac{3p}{\pi N} \cdot \frac{l^2}{d^2}$$

TURBINE GEARS.
FIG. 26
FIG. 27.
FIG. 28.
FIG. 29.
FIG. 30.

There are two cases to consider: the case where there is no centre bearing and the pinion is supported from the ends, as in fig. 27, and the case where there is a centre bearing, as in fig. 28.

The deflection of the pinion can be calculated in the usual way, and is shown by the curves *ae* and *fg*. To this must be added the twist, as shown by the curves *ab* and *cd*. Adding these together, the total distortion is shown by the shaded area, the maximum distortions in each half of the pinion being δ_1 and δ_2. The gap shown in the middle of the pinion is to enable the hob to clear the teeth in each half.

If, in the case of a pinion with a centre bearing, the pinion took up the position *abcd*, shown in fig. 30, the effect of the distortion of the pinion is reduced.

In the case of a pinion without a centre bearing, the effect is only small, as shown in fig. 29.

In the case of a pinion without a centre bearing the bending is the chief consideration, whereas in the case of a pinion with a centre bearing the twist is the chief thing.

WORM GEARING.

There are two types of worm gear—namely, one in which the worm is parallel throughout its whole length and the other in which the worm is curved along its face to suit the curvature of the worm wheel. The former is known as the ' parallel ' worm gear, and the latter as the ' Hindley ' or ' globoidal ' worm gear.

The introduction of machine-cut worm gear of high precision and the increased knowledge of the nature of tooth contacts has resulted in the use of worm gear for the transmission of large horse-powers, with very high efficiencies.

Formerly it was considered correct to make the threads of all worm gear straight-sided on a linear section through the axis of the worm, and to take the pitch line midway down the working depth of the threads; thus, for the parallel gear this section showed the threads to be a pure rack, and for the globoidal gear a similar rack formation but with the threads pointing radially to the

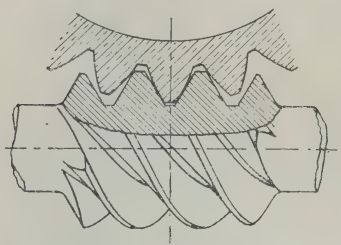

FIG. 31.—Parallel Worm Gear.

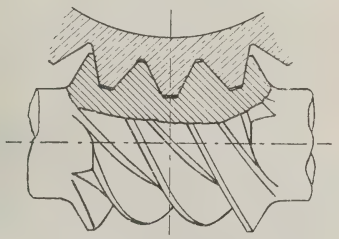

FIG. 32.—Hindley Worm Gear.

centre of the worm wheels. Actually these two types are very closely related because a parallel worm can be regarded as being a globoidal worm which has been made to suit a worm wheel of infinite diameter.

The construction of the threads of the parallel worm to correspond to that of a rack gives involute profiles to the worm-wheel teeth on the central section, as shown in fig. 31, and with the Hindley gear, shown in fig. 32, a shape corresponding to the threads of the worm, consequently giving teeth in simultaneous contact. It would therefore appear as if these two types were quite correct in every way: involute tooth engagement for the parallel worm, and a complete tooth engagement for the Hindley worm. Actually these conditions only apply on the central plane. Neither is the involute tooth profile nor the attractiveness of the Hindley type maintained; their value is entirely lost on all other planes owing to the curvature of the face of the worm wheel. Whenever straight-sided threads are used for worms, whether for the parallel or the Hindley type, the teeth on other planes than the central one are not, and cannot be, wholly conjugate to the threads of the worms, because the hob during cutting unavoidably removes too much metal from the wheel teeth. The result is that in actual practice neither of these worms transmits uniform velocities to the worm wheels, and instead of the contact being mainly on the leaving side it is almost wholly on the entering side, thus giving a higher coefficient of friction and a lowering of the overhaul efficiency of the gears. Worm gear, unless correctly designed, does not transmit a uniform velocity from one member to another. A close approximation is obtained with gears of comparatively fine pitch, and in those of a high lead angle any error is

sometimes concealed by the adjacent thread being in action in such a manner that by sustaining an extra proportion of the load distribution the variable velocity period is tided over. Even the inertia of the parts may prevent a change in the velocity of the engaging pair, but this is detrimental to the gears. To consider a worm gear as a kind of a development from the screw is fundamentally wrong. The pitch surfaces of the worm gear are cylinders lying at right angles to each other, hence they only touch at one point, whereas in a screw and nut the pitch surfaces coincide. Expressed in simple language, one can say that, consistent with the transmission of uniform velocity, the normal to the surfaces from the point of contact must always cut the central plane which contains the axis of the wheel, at a point on the straight line lying on the wheel pitch cylinder, and consequently tangential to the pitch cylinder of the worm. Thus, for every point of intersection between a worm thread and the zone of contact, there is a definite relation between its angular and longitudinal positions. If contact takes place at any other point than this intersection, it does so to the detriment of the transmission of uniform velocity.

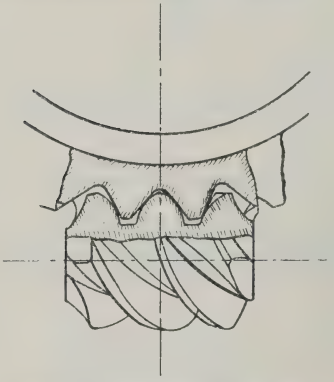

FIG. 33.—' D.B.S. Patent Worm Gear.'

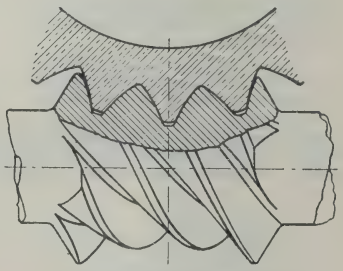

FIG. 34.—Enveloping Worm Gear.

The mathematical investigations carried out by Mr. F. J. Bostock have shown that the usual rack formation of the threads of the parallel and the globoidal worms is entirely wrong. Fig. 33 shows the correct form of worm threads for the parallel worm, and is known as the ' D.B.S. Patent Worm Gear,' manufactured by Messrs. David Brown & Sons (Huddersfield), Ltd. In this gear, instead of the threads being straight-sided on a section containing the axis of the worm, they are straight-sided on a section taken at a predetermined distance away from the axis, and the pitch line, instead of being half-way down the working depth, is taken at the bottom of the working depth or at the throat diameter of the worm wheel. This gear has been largely used for the propulsion of buses and lorries in this country and America, and upon test by the N.P.L. gave an efficiency of 97·3 per cent.

The corresponding correct form of threads for the globoidal type is shown in fig. 34, which was also the result of Mr. Bostock's investigations, and is manufactured by Bostock & Bramley, Leeds.

Although the ordinary involute type of parallel worm gear has certain inherent defects, it is still largely used for drives in which the maximum load-carrying capacity and efficiency are of little importance.

Definitions.

' *Gear Ratio*' :—

$$\frac{\text{No. of teeth in wheel}}{\text{No. of starts on worm}}$$

If worm is single threaded, no. of starts is 1; if double threaded, no. of starts 2, and so on.

' *Worm-pitch cylinder and worm-wheel pitch circle*' (fig. 35).—The worm-pitch cylinder is a virtual cylinder which makes contact with the worm-wheel pitch circle at a point lying on a line through the axis of the worm wheel and perpendicular to the worm axis.

' *Centre distance* ' is the distance between the axis of the worm and the centre of the worm wheel.

'*Axial pitch of worm threads*.'—The distance between the centre lines of two adjacent threads taken on an axial section.

'*Normal circular pitch of worm threads*' is the distance between the centres of adjacent threads measured round the pitch cylinder and normal to the helix.

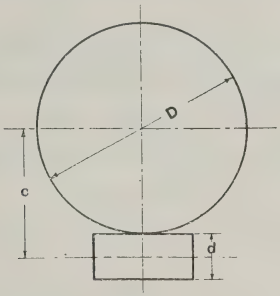

FIG. 35.

'*Worm lead angle*' is the slope of the helix, and is the angle between the helix and a plane perpendicular to the worm axis (fig. 36); lead angle = α.

'*Worm spiral angle*' is the complement of the lead angle = θ (fig. 36).

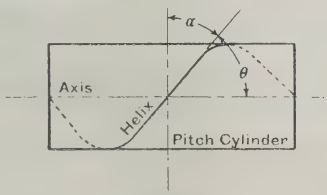

FIG. 36.

'*Axial pressure angle*' is the angle of inclination of worm profile at any point on an axial section to a perpendicular to the worm axis = ϕ (fig. 37).

'*Normal pressure angle*' is the angle between a tangent plane at any point on tooth profile, and a perpendicular to the axis at that point.

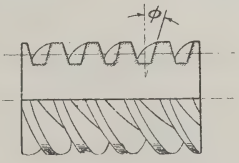

FIG. 37.

'*Lead of worm*' is the linear distance of advancement parallel to the axis of each thread of the worm per revolution of the worm.

'*Circular pitch of wheel teeth*' is the distance between the centres of adjacent wheel teeth measured round the pitch circle.

'*Clearance*' at worm wheel tooth base as for spur gears.

'*Worm thread addendum.*'—Height of thread above pitch cylinder.

'*Worm thread dedendum.*'—Depth of thread below pitch cylinder.

'*Worm crest diameter.*'—The overall dia. of the worm threads.

'*Worm root diameter.*'—The dia. of the worm at the root of the threads.

'*Wheel throat diameter.*'—The diameter of wheel rim at the bottom of the curved tooth face.

'*Wheel tooth throat addendum.*' The distance between the pitch circle and top of teeth on a centre section normal to the wheel axis.

'*Wheel tooth overall addendum.*'—The addendum measured to overall dia. of rim.

'*Wheel teeth dedendum.*'—The distance between the pitch circle and the bottom of the tooth spaces measured radially and on a central plane.

'*Wheel overall diameter.*'—The greatest dia. of wheel rim.

'*Wheel root diameter.*'—The dia. at the base of wheel teeth.

Design.

In the common type of worm gear, in which the straight-sided thread on the axial section is used, the 14½° axial pressure angle is generally adopted. The cross-sectional dimensions of the worm thread are commonly made the same as the 14½° rack teeth—i.e. addendum $= \frac{1}{dp}$; dedendum $= \frac{1}{dp}$ + clearance; clearance = ·155 module. If the lead angle used is greater than 20°, then the proportions are based on the normal pitch. If a 20° lead angle is adopted, then 14½° pressure angle is too small to give satisfactory results. For automobile drives a 30° pressure angle is usually adopted.

If the worm is to be cut on a shaft direct, then the pitch dia. must be such as to give sufficient strength to make the shaft rigid, and strong enough to carry the torque with the requisite margin of safety. The root dia. must be such as to prevent serious deflection when carrying the load.

The width of face of the worm wheel should be as wide as is reasonably possible, compatible with general design of gear.

The throat should not envelop root of worm by more than about 1·5 times the module, otherwise the wheel teeth will be cut to a sharp edge.

Calculations.

To compute gear ratio, revs. of worm and wheel being given:—

R = revs. per min. of worm; r = revs. per min. of wheel;

$$\text{Gear ratio} = \frac{R}{r}.$$

To compute no. of wheel teeth N, when gear ratio is given and no. of worm starts, n,

$$N = \text{Gear ratio} \times n.$$

To compute worm pitch dia., given centre distance and worm lead angle, α.

$$d = \frac{2 \text{ centre distance}}{1 + [\text{gear ratio} \times \tan \alpha]}, \text{ approx.}$$

If centre distance and wheel pitch circle dia. is given,

$$d = 2 \text{ centre distance} - p.c.d. \text{ of wheel.}$$

To compute the circular pitch of wheel teeth (p), given $p.c.d.$ of wheel D and no. of teeth N,

$$p = \frac{\pi D}{N}.$$

To compute the pitch dia. of wheel when circular pitch and no. of teeth in wheel are given,

$$D = \frac{pN}{\pi}.$$

To compute the centre distance when the pitch dia. of worm is given and the pitch circle dia. of wheel,

$$C = \frac{D + d}{2}.$$

To compute the lead of a worm, given the pitch and number of starts of worm (n),

$$\text{Lead} = \text{pitch} \times n.$$

To compute lead of worm, given the pitch dia. of wheel and the gear ratio,

$$\text{Lead} = \frac{\pi D}{\text{Gear ratio}} = \frac{\pi D n}{N}.$$

To compute the worm lead angle, given the pitch dia. of worm and worm lead,

$$\tan \alpha = \frac{\text{Lead}}{\pi d}.$$

To compute normal circular pitch, given the pitch and lead angle α,

$$n.c.p. = p \cos \alpha.$$

To compute worm thread addendum and dedendum on wheel throat addendum, given the pitch of the wheel teeth,

$$\text{Add.} = \cdot 3183p\,; \quad \text{Ded.} = \cdot 3683p.$$

If α exceeds 20°, Add. $= \cdot 3183\ n.c.p.$; Ded. $= \cdot 3683\ n.c.p.$

To compute worm crest dia., given worm pitch dia. and addendum,

Worm crest dia. $= d + 2$ addendum; Worm root dia. $= d - 2$ dedendum.

To compute wheel throat dia., given pitch dia. of wheel and wheel tooth throat addendum,

Wheel throat dia. $= D + 2$ wheel tooth throat addendum.

To compute overall dia. of wheel, given pitch circle dia. of wheel and wheel tooth throat addendum,

Overall dia. of wheel $= D + 3$ wheel tooth throat addendum.

To compute wheel root dia., given pitch dia. of wheel and wheel tooth dedendum,

Wheel root dia. $= D - 2$ wheel tooth dedendum.

Worm-wheel peripheral velocity, $V_w = \cdot 262\ DN'$ ft. per min.

Worm peripheral velocity, $v_w = \cdot 262\ dn'$ ft. per min.

where $N' =$ no. of revs. per min. of worm wheel, and $n' =$ no. of revs. per min. of worm.

Rubbing velocity at pitch point,

$$V_R = \sqrt{V_w^2 + v_w^2} = \frac{v_w}{\cos \alpha}.$$

Let,

$T =$ torque on shaft transmitting H.P. horse-power at N revs. per min.,

Then,

$$T = \frac{63{,}025 \text{ H.P.}}{N} \text{ lb. ins.}$$

Also,

$$T = \frac{\pi d^3}{16} fs,$$

where $d =$ shaft dia. in ins.; $fs =$ safe shear stress for the material.

Neglecting bending and other stresses,

$$d = \sqrt[3]{\frac{16\,T}{\pi fs}}; \quad \text{H.P.} = \frac{2.\pi.N.T.}{33{,}000 \times 12}.$$

FORCES ACTING BETWEEN WORM AND WHEEL.

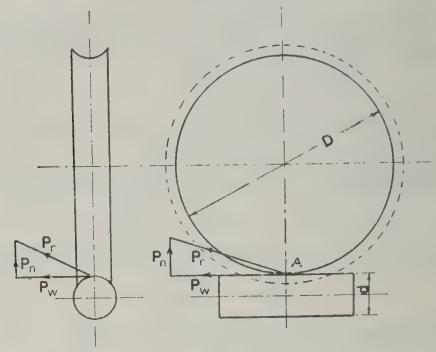

FIG. 38.

It is assumed that the resultant reaction between the worm and wheel passes through the pitch point A.

Resultant reaction = P_r; resultant force acting parallel to wheel axis = P_W; resultant force acting parallel to worm axis = P_w; force acting perpendicular to both axes = P_p; R = Gear ratio. T = torque due to H.P. in lb. ins.

Approximately,

$$P_w = \frac{2RT}{D} = \frac{2TN}{D_n}; \quad P_W = \frac{2T}{d}; \quad P_p = P_w \tan \phi.$$

The efficiency is approximately $= \dfrac{\tan \alpha}{\tan (\alpha + \lambda)}$,

where λ = angle of friction.

The maximum efficiency occurs when the lead angle is about 45°.

Worm and Worm-Wheel Manufacture

WORM.

A comparison of the parallel and globoidal worms will at once show that two distinct methods of production are necessary.

In the former case the worm 'blank' can be run past a rotating cutter whilst the 'blank' is traversed in a helical track. Finishing can be effected by substituting a grinding wheel for the cutter. In the latter case the 'blank' must be rotated at uniform speed whilst the cutter moves about a centre which must be accurately located relative to the 'blank,' and at the same time adjustable.

Worms are usually supplied solid with the shaft, a bearing being provided on each side of the worm and close to it.

To ensure perfect concentricity of shaft journal and worm it is common practice to grind both the journal and the outside of the worm blank before the actual cutting is made.

Special machines are in use for worm milling. The worm is made to move in a helical path before a rotating cutter. A thread space is milled for each longitudinal traverse of the table. The arbor is carried in a swivelling head, which enables it to be set at any angle to meet the spiral of the worm to be cut.

CUTTER FORM GENERATION.

The rotary cutter at first sight appears to be quite a straightforward matter, with its contour made to correspond with the space of the worm thread. Such, however, is far from being the case, as its actual contour is quite different from the thread space which it cuts in the worm blank, as

will be seen from fig. 39. This apparent paradox is caused by the interference of the cutter with the side of the worm thread, and it will be understood when it is remembered that the worm thread is an endless spiral. As a rotary cutter must be circular in shape, and as a circle and spiral cannot coincide, it is obvious that the contour of the circular cutter cannot coincide with the thread space of the spiral worm. The base of the worm thread system is a straight line. In the system of cutter generation a straight edge tool is set to an angle corresponding to the pressure

FIG. 39.—Worm and its Cutter.

angle of the worm to be cut, and is then made to traverse in a spiral path corresponding exactly with the spiral of the worm. Thus a generating tool is mounted in a worm milling machine in the same position and manner as the worm which is to be cut, its straight edge accurately representing one side of the worm thread. When it has generated one side of a white metal blank it is indexed to the other side, thus forming the contour of the required cutter.

WORM WHEEL.

The production of a worm wheel of accuracy is a far more difficult process than that of producing a worm.

Worm wheels are produced by the process of hobbing, the hob being similar in form to the worm. A parallel hob having teeth of constant shape throughout its length provides the best means of securing accuracy, which is essential to obtain the best results from the worm gear.

The hob is made by the same process as the worm, and is hardened and afterwards ground. The production of a hob for the globoidal worm wheel is very difficult, and generally the accuracy of the finished job is not of the highest order. Often for these hollow worm wheels the single cutter is used, but of course the result is only an approximation to the true tooth profile. The cost of the hollow type of worm gear is rendered more expensive by the complications arising from the required shapes, and accuracy is much less likely than with the parallel worm.

HOBS—MANUFACTURE AND SHARPENING.

The teeth of worm wheels are of such construction that they do not lend themselves to operations of planing, shaping, or milling like other forms of gearing: they can only be produced by a process of generation by means of a cutting tool called a 'hob.' Whilst it is true that the spiral angle pitch, the number of threads, and pitch diameter in the hob must correspond with that of the worm, yet both the outside and bottom diameters of the hob are made larger in order to provide requisite clearance in the roots of the teeth. The hob throughout is gashed along its length normal to the spiral angle for the purpose of providing a cutting face, whilst the teeth are relieved in order to provide a cutting clearance. As the shape and contour of the wheel teeth are entirely dependent upon the design and accuracy of the hob, it is necessary that this tool should receive the most careful supervision in all stages of its manufacture and subsequent regrinding. Hobs are generally made with their cutting faces radial; it is therefore essential that they should be sharpened radially, or an alteration in shape will result. The same, of course, applies to ordinary rotary cutters. It will be appreciated that as a hob is sharpened its diameter is reduced, but with a reamer hob the reduction in diameter is only a few thousandths of an inch in the whole length of the teeth, thus uniformity of shape is retained.

WORM WHEEL GENERATING.

Generally the worm wheels are rough turned on automatics and turret machines, and pass from thence to the worm-wheel section for rough cutting of the teeth, after which they are finished, turned, and finally the teeth undergo a reamering or finishing operation. In no small measure is the interchangeability and high efficiency of the wheels due to this reamering operation.

The generating of the teeth of the worm wheel is carried out in a machine as illustrated in fig. 40, the blank being mounted upon a revolving table, which is positively driven at a predetermined speed, according to the ratio of the gears being cut, whilst the hob is caused to travel longitudinally across the face of the wheel. Owing to the spiral of the hob it is necessary

to compensate for its longitudinal travel by means of a differential, whilst the rate of travel or feed can be varied at the will of the operator.

A special feature of the mounting of the worm wheel on the table is made. A hardened and ground micrometer adapter carries the arbor, which supports various other adapters to suit the locating register of the worm wheel blanks, the micrometer being adjusted until the specified distance from the locating face of the blank to the axis of the hob is obtained.

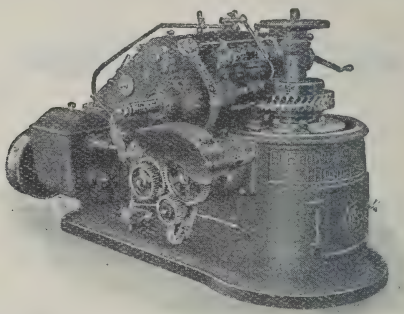

FIG. 40.—Worm Wheel Generator (*David Brown & Sons (Huddersfield), Ltd.*).

To facilitate setting up, and to test the true running of the registers and worm-wheel blank, the drive to the table is arranged so that it can be disconnected in order that the operator may be able to revolve the table by hand and so, by means of a clock indicator, test the accuracy of the mounting.

The head which slides horizontally along the bed towards the worm wheel contains the whole of the mechanism for driving the hob and traversing the hob slide. The latter is mounted on the head at an angle normal to the direction of the stress, so as to present the maximum bearing area to the very best advantage.

The main drive is taken from a single pulley fitted with an internal friction clutch in conjunction with a four-speed gear box. The drive is then transmitted in one case directly to the index change wheels for driving the table, and in the other to the worm wheel mounted on the hob spindle.

It should be mentioned that the dividing wheel is of greater diameter than the largest blank which the machine will cut, and a neat design is effected by allowing the cuttings to fall through the arms of the table into the bed of the machine, from whence the cutting lubricant is drained.

Worm and Wheel Inspection.

For testing the accuracy of the pressure angle a knife edge protractor is placed along the side of the thread and the angle read to plus or minus a few minutes. This is carried out in a worm gear testing machine, illustrated in fig. 41, which has been designed to enable the various testing operations to be performed on both worms and wheels. These can be tested separately as individual pieces, or in combination when mounted together at the specified centre distance. The bed consists of two slides at right angles, one carrying a pair of adjustable centres and the various testing appliances, whilst the other slide carries an adjustable arbor adapter, which is controlled by a micrometer screw, enabling it to be set at any required distance from the other slide, so giving correct centres for the worm and wheel under test. This machine is most conveniently operated, as it can be worked from either side, thus allowing the operator to be in the most advantageous position to carry out all the necessary tests. Other instruments are used on it for testing concentricity and lead.

The process of case-hardening worms is exactly the same as for other work, but although every precaution be taken some little distortion is bound to occur. They therefore require straightening so that their pitch diameter runs true; for this purpose a clock indicator on a testing machine is used in conjunction with the straightening press, and by means of a ball placed in the space this operation can be accurately and quickly performed.

Interchangeability of the worm wheel is ensured by the use of a double ball micrometer, which measures the comparative pitch diameters.

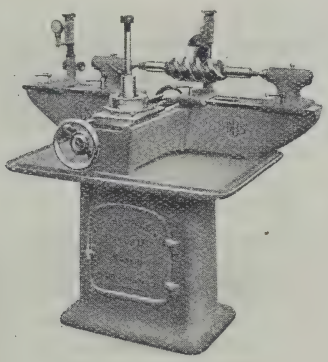

Fig. 41.—Testing Worm for Accuracy of Pressure Angle, Tooth Thickness, and Contour (D. B. S.).

The final inspection is made on a testing machine, where the gears undergo a more rigorous test. The wheels are tested for concentricity of cutting and the distance from the centre of the worm axis to the locating face, after which they are tested together to verify the centre distance.

Worm Gear Application.

Worm reducing gear units are with great advantage coupled direct to electric motors, enabling reductions in speed from 4 : 1 to 100 : 1 in a silent and efficient manner, and when both of them are mounted on the common baseplate they represent a simple, sound, and economical proposition.

On account of their ability to withstand considerable overload for short periods they lend themselves admirably for intermittent work, because for the work they are called upon to do they can be made relatively small; therefore they are of great use in crane work and for starting purposes of electric motors, steam, gas, and oil engines.

Horse-Power Formula.

$$H.P. = K \times A \times T \times r^{\frac{8}{3}} \times R^{\frac{8}{3}} \times S,$$

where,

K = constant; A = projected area of worm wheel in sq. ins.; T = teeth in contact; r = pitch radius of worm in ins.; R = revs. per minute of worm; S = function of lead angle.

For K, use:

Hardened	mild steel worm and	phosphor-bronze wheel	K = 0·14
Soft	" "	" "	K = 0·1
Hardened	" "	cast-iron wheel	K = 0·08
Soft	" "	" "	K = 0·07

For intermittent work multiply the above by 1·3.

For T, use:

Worm Threads	1	2	3	4	5	6	7	8
T	1·4	1·5	1·66	1·8	1·9	2	2·1	2·2

For S, use:

Lead Angle	5°	10°	15°	20°	25°	30°	35°	40°	45°
S	0·09	0·18	0·27	0·36	0·45	0·55	0·65	0·77	0·9

Location.

The parallel worm is not seriously affected by slight inaccuracy in the centre distance, and does not need special precaution with respect to endwise movement.

The globoidal form, however, needs accurate location in all directions in order to work correctly. Further, when dismantling the worm and shaft cannot be removed bodily as is the case with the parallel worm.

Finishing.—It is essential that worm threads have a very hard case, and must be ground to produce a highly polished surface. Hence the selection of suitable material is of prime importance. Generally worms machined from solid steel forgings give best results. Particular care is also required in the hardening processes in order to avoid, as far as possible, serious distortion.

EXAMPLE.—Obtain the dimensions of a worm for a gear ratio of 10 : 1 when the centre distance is 8 ins.

Assume number of worm threads = 5 = n, then no. of teeth in wheel = 50 = N. Assuming lead angle = 45°.

$$\text{Let } \frac{\text{pitch dia. of worm}}{\text{module}} = m. \quad \text{Then } \frac{n}{m} = \tan 45° = 1.$$

$$m = n = 5. \qquad \text{Also N} + m = \frac{2c}{\text{module}}.$$

$$\therefore \quad \text{module} = \frac{16}{55} = \cdot 29, \text{ for which a module of } \cdot 3 \text{ would be used.}$$

Pitch dia. of worm = $1\frac{1}{2}$ ins.; dia. of worm wheel = $6\frac{1}{2}$ ins.

REDUCTION GEAR.

H-R Gear.

(J. Stone & Co., Ltd., Deptford, London, S.E. 14.)

With this gear, using the worm gear as its base, it is possible to give any speed ratio in a very compact size, *i.e.* in the small space of 12 ins. × 12 ins. × 12 ins., any ratio up to 20,000 to 1 can be obtained, while for larger ratios compound gears take up little or, in some cases, no more space than for small ratios.

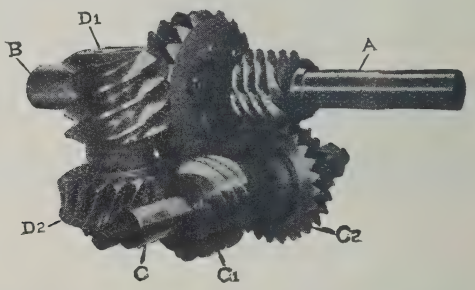

FIG. 42.

The arrangement adopted in a standard type of reduction gear is shown by fig. 42. The driving shaft A transmits power from the prime mover through a worm mounted on the shaft to a worm wheel C, arranged on shaft C. The shaft C is extended to carry a worm C_1, and the power is transmitted through this worm to a worm wheel D_2, mounted on shaft D transverse to the shafts A and C. This shaft in turn carries a worm D_1, which transmits the power through a worm wheel arranged on the driven or slow speed shaft B, so that the essence of the invention is the placing of gear shafts around the periphery of the driving worm and the driven worm wheel, thus permitting the first and final shafts to be arranged co-axially.

The efficiency of the gear is 70 to 90 per cent. in gears having ratios up to 250 to 1. This efficiency is maintained throughout the life of the gear. As the gear is always running in an oil-bath and its design is such that low tooth pressure and efficient helix angles are obtained, it is durable and silent in operation.

There are over 300 standard H-R Gear ratios, from 10 to 1 to 50,000 to 1, to select from.

In addition to secondary motion shaft, intermediate drives, both vertical or horizontal plane, may be incorporated in any standard box.

Ratios from 10 to 1 up to 50,000 to 1 can be obtained in standard gear-boxes. The size of a particular gear-box for a given ratio or load-carrying capacity is very compact and is claimed to be smaller than any other type of gear.

Since each gear ratio represents only the cube of the actual ratio required, only a small ratio on each train of gears is necessary, consequently exceedingly efficient worm lead angles are obtainable; thus with a gear ratio 64 to 1, each train of gears requires a ratio of 4 to 1 and a lead angle of 45°, each gear train having an efficiency of 95 per cent., so that the over-all efficiency would be not less than 85 per cent. With the ordinary type of worm gear having a single worm and wheel, for such a gear ratio only a single start worm could be employed having a lead angle of, say, 7°, which would give an efficiency of not more than 65 per cent. Even if very fine pitch and a 2-start worm were employed, it would be impossible to obtain an efficiency exceeding 75 per cent.

An exceedingly important feature of the H-R Gear, particularly where employed with large ratios and where space restrictions come in, is its load-carrying capacity. The maximum permissible loading on any worm-gear tooth depends entirely upon the rubbing velocity, and it will be seen that in the H-R Gear the rubbing velocity of the final worm and worm wheel is broken down very considerably through the first two trains of gears. In addition, because of the comparatively small ratios on each train, the minimum number of teeth and maximum pitch can be employed. On the very large ratio gears it is possible to load the gear teeth almost up to the yield point of the material of the worm wheel.

The H-R Gear is claimed to be the only absolutely silent gear which provides for a co-axial drive; this, in many cases, is a most important feature.

The gear has been applied to every kind of machinery.

H.-R. Balance Drive Gear.

(J. Stone & Co., Ltd., Deptford, London, S.E. 14.)

Although not providing the highest speed ratios obtainable with the H.-R. Standard Gear, this gear possesses several important additional advantages. The final gear-wheel is driven by two distinct elements which by a special patented arrangement are always in driving contact. By such an arrangement the gear is capable of transmitting double the torque of the ordinary gear. Further, the arrangement secures elimination of the radial load on the final shaft.

The worm-wheel A (fig. 43) is driven by two worms, B1, B2. These latter have connected at

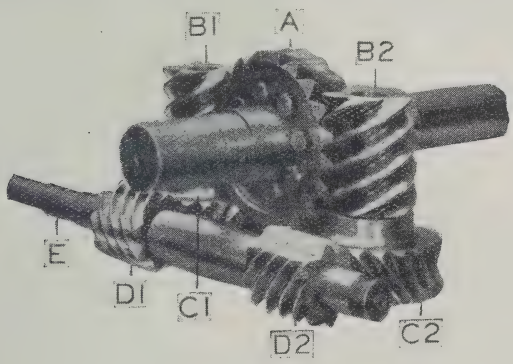

Fig. 43.

their lower extremities worm-wheels C1, C2. C1 and C2 are in engagement with worms D1 and D2 mounted on high-speed shaft E. Since worms B1 and B2 are in engagement on opposite sides of A they rotate in opposite directions, and must therefore have opposing lead angles. This also applies to worm-wheels C1 and C2. Similarly, worms D1 and D2 have opposite leads and oppose one another. The thrusts are therefore balanced, and eliminate the necessity for special precautions in this respect.

All the advantages are secured as with the H.-R. standard gear as regards silence, efficiency, etc.

Max. speed ratio with the balanced gear 250 to 1
Min. „ „ „ „ „ 5 to 1

The gear is specially applicable to heavy duties where shock is present, such as for rolling-mills, main drives for stern wheel paddle-boats, conveyors, etc.

VARIABLE-SPEED GEAR.

The 'VSG' Mark III. Hydraulic Variable-Speed Gear.

(*The Variable Speed Gear Ltd.*, 6 *Broadway, Westminster, London, S.W.* 1.)

This gear consists of two units, viz. an 'A' end or pump unit (fig. 44), and a 'B' end or hydraulic motor (fig. 45). These 'A' and 'B' ends can be opposed to one another directly with a common connecting plate termed a 'valveplate,' forming a type 'C' gear, or they can be separated to any reasonable distance and connected by piping, each unit having a separate valveplate, forming a type 'K' gear.

The flexibility of arrangement possible with the 'VSG' gears is a valuable feature, particularly so where considerations of space enter into account. Oil, which is practically incompressible, is the medium of transmission of power, and as this is supplied under pressure to the most important working surfaces and the whole of the machine casing is filled with oil, lubrication is perfect and wear negligible.

In certain instances machines are arranged to run with empty cases, and when this is so, special arrangements are made for the lubrication of the working parts.

Construction.

The 'B' end or hydraulic motor is generally similar in construction to the 'A' end or pump unit, which is fully described in the 'Pump' section, p. 1274, a number of its components being identical with those of the 'A' end. For the majority of purposes no controls or relief valves are necessary in the 'B' end, and the tilting box is usually fixed, giving the 'B' end a fixed capacity.

Where cooling is desirable, a water cooling coil is fitted in the 'B' end around the cylinder barrel.

Whilst in some cases 'Michell' type bearings are fitted to take the axial and radial thrust behind the socket ring in the 'B' end, in certain equipments 'VSG' 'B' ends are fitted with roller bearings.

Operation of the Gear.

When a 'VSG' gear is ready for running, the entire space within the cases and valveplate of the type 'C,' and valveplates and piping in the type 'K,' is filled with oil.

A definite portion of the oil is enclosed within the 'cylinders' ahead of the pistons, valveplate port passages, and piping of type 'K.' This is the working oil used in transmitting energy, the case oil not being subject to pressure.

Assuming the tilting box with its socket ring is set at the neutral position (*i.e.* perpendicular to the mainshaft), the 'A' end mainshaft, if rotated, will carry with it the socket ring and the cylinder barrel, together with the pistons and connecting rods. The pistons will not reciprocate or move to and fro in the cylinders, and as there will be no delivery from the pump, the 'B' end will remain stationary.

If the control be moved a little, so as to move the top of the tilting box away from the 'valveplate,' and the 'A' end mainshaft is rotated in a clockwise direction (looking on its shaft end) all the pistons as they move down on the right-hand side will be driven in towards the valveplate, expelling the oil contained in the cylinders through the cylinder ports and the large port in the same side of the valveplate. The 'B' end, as is explained later, will then commence to rotate at a speed corresponding to the amount of delivery given by the 'A' end.

The pistons on the left-hand side of the 'A' end will, as they ascend, be drawn away from the valveplate, and their cylinders will fill with oil from the valveplate port facing them.

It should be noted that when a piston reaches the top or highest position in its revolution, and also the lowest position, it for an instant makes no end movement. This corresponds with the cylinder port crossing the top or bottom lands or spaces between the two valveplate ports.

The quantity of oil forced through the valveplate port depends upon the length of stroke imparted to the pistons and consequently upon the angle at which the tilting box stands.

The 'B' end is an inversion of the 'A' end, and the 'B' end socket ring is carried normally at a fixed angle of about 20°, the top of the tilting box lying back from the valveplate, and when the 'B' end mainshaft is rotated the 'B' end pistons will make their full stroke as they pass between the bottom and top pistons.

The oil expelled by the 'A' end pistons through the pressure port of the valveplate enters the 'B' end cylinders facing that port and exerts pressure on the pistons in those cylinders.

Due to the socket ring being housed in the tilting box, the pistons cannot move except by rotating the socket ring in its bearings on the inclined plane, thereby converting the reciprocating motion of the pistons into rotary motion of the socket ring and the shaft to which it is connected.

The socket ring therefore revolves and carries with it the mainshaft to which it is connected by the universal joint. The 'B' mainshaft in turn rotates its cylinder barrel, and the whole of the 'B' end rotating group revolves in the opposite direction to the rotation of the 'A' end mainshaft.

The speed of rotation of the 'B' end mainshaft depends upon the quantity of oil delivered by the 'A' end. For example, if each cylinder has a capacity of, say, 3 cu. ins., one complete revolution of the 'B' end group of 11 cylinders would transfer 33 cu. ins. of oil from the right-hand side to the left-hand side. If the top of the 'A' end tilting box be tilted away from the valveplate

THE 'VSG' MARK III. HYDRAULIC VARIABLE-SPEED GEAR.

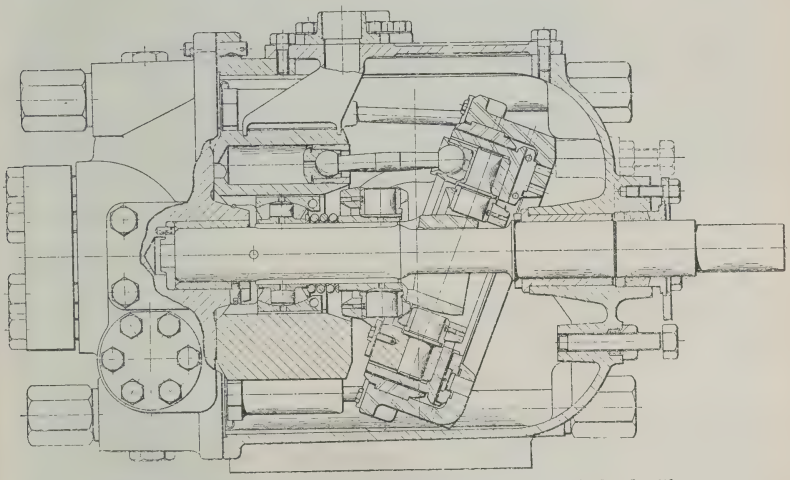

FIG. 44.—Vertical section through 'VSG' Mark III. 'A' end, fitted with lever control.

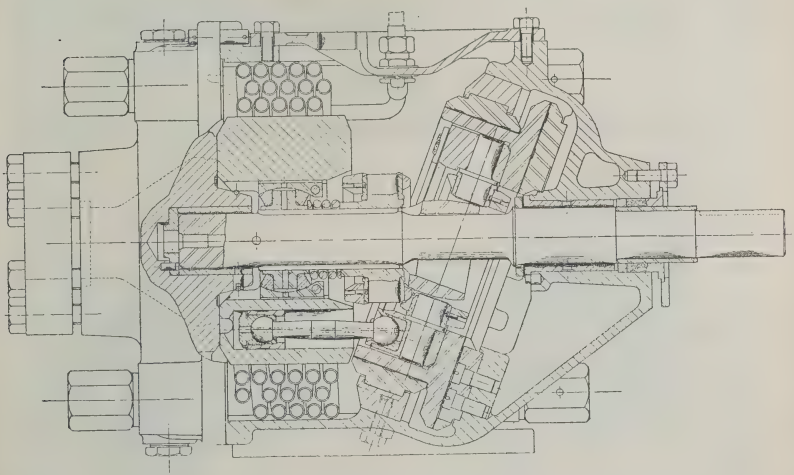

FIG. 45.—Vertical section through 'VSG' Mark III. 'B' end, fitted with Michell type bearings.

sufficiently to cause the socket ring to impart a small stroke to the ' A ' end pistons corresponding to an output from each cylinder of, say, 0·01 cu. in., all the 11 pistons of the ' A ' end will together transfer 0·11 cu. in. of oil from the left-hand to the right-hand side at each revolution of the mainshaft.

On the basis of the capacity of the ' B ' end cylinders per revolution being 33 cu. ins., 300 revs. of the ' A ' end mainshaft at this degree of tilt will be necessary to rotate the ' B ' end mainshaft once. If, however, the ' A ' end socket ring be tilted still farther, the output of the ' A ' end will be greater and the ' B ' end mainshaft will rotate proportionately faster, until at full stroke both ends are at the same speed.

So far reference has been made to tilting the ' A ' end socket ring in one direction only, namely, by moving the top of the tilting box away from the valve plate. If, however, it be moved in the opposite direction, the oil will be discharged through the left-hand port instead of through the right-hand port as previously ; this will cause the ' B ' end group to rotate in the opposite direction to that in which it has previously revolved, and it will now correspond in direction of rotation with the ' A ' end mainshaft—viz. clockwise. The gear is therefore fully reversible.

When the ' A ' and ' B ' ends are of equal capacity, the maximum speed of the ' B ' end mainshaft will be equal to that of the ' A ' end, forward or reverse as required.

For some purposes ' A ' and ' B ' ends of different capacity are combined, usually a large ' B ' end being employed, thereby giving a fixed reduction ratio as well as variable and reverse speeds.

Where a reduction or step-up gear is necessary on either the input or output shaft of the gear, this can, in many cases, be arranged within the gear casing.

Control.

Various types of control can be fitted, the purpose of all of which is to vary the angle of the ' A ' end tilting box, and thereby the delivery of the pump. The most usual forms of control are :—

(1) *Lever.*—A simple lever mounted directly on an extension of one of the tilting box trunnions.

(2) *Wheel or Rotary.*—Comprising a shaft carrying a pinion engaging a toothed sector fitted to the top of the tilting box. On this shaft is mounted a handwheel for direct manual operation, or sprocket, bevel, etc., for distant or mechanical control.

(3) *Automatic or Pressure Control.*—This consists of a hand or mechanically operable control combined with an automatic pressure operated device which regulates the speed of the gear automatically to suit the load and obviates the necessity of using skilled operators to safeguard equipments dealing with widely fluctuating loads.

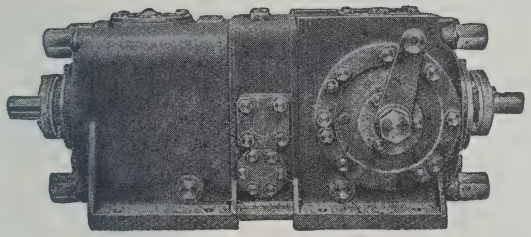
Advantages.

The special properties of the ' VSG ' Hydraulic Variable Speed Gear can be summarised as follows :—

(1) Speed change without declutching from prime mover.
(2) Ability to ' inch ' and rotate at very low speeds.
(3) High torque at low speed.
(4) Perfectly smooth acceleration and retardation at any constant or variable rate.
(5) Quick reversibility without shock.
(6) Complete positive and simple control in either direction.
(7) Steady speed under fluctuating loads.
(8) Enables constant speed non-reversing prime mover to be used.
(9) Protects complete installation from damage due to overloads.
(10) Reduces labour and operating costs.
(11) Repairs and maintenance negligible.

An important feature inherent in the ' VSG ' gear is the braking effect which can be obtained when it is used with a regenerative prime mover, enabling the retardation of masses having large momentum and unbalanced loads to be carried out under absolute control, *e.g.* in the case of a hoist, loads may be lowered at any desired speed, decelerated and held in all positions without the use of mechanical brakes. In fact, the same degree of control is available when lowering as when hoisting.

With electrically driven machinery a distinct advantage is obtained by the use of the ' VSG ' gear, inasmuch as the simplest and cheapest type of motor can be installed, *i.e.* squirrel cage induction or shunt wound DC., also controllers and resistances with their attendant heavy current losses are dispensed with, a light load starter only being necessary. Current peaks when starting heavy loads are eliminated.



Type "C" "VSG Mark III" Variable Speed Gear, fitted with Lever Control.

"VSG"

HYDRAULIC VARIABLE SPEED TRANSMISSION GEARS

Infinite variation of speed without steps, forward and reverse. Perfect and easy control. High starting torque. Low maintenance costs. Eminently suitable for controlling machinery for industrial purposes, viz.:—

Annealing Furnaces
Cable-Making Plant
Colliery Plant
Conveyors
Coilers for Belts, etc.
Foundry Plant
Floorcloth Machinery
Iron & Steel Works Machinery
Linoleum Machinery
Paper-Making Machinery
Photographic Paper and Film Treating Plant
Printing Machines
Rubber Machinery
Textile Machines
Wire-Making Machines
Woodworking Machines

Also for Ship Machinery, including Steering Gears, Windlasses, Capstans, Boat Hoists, Winches, etc.
Extensively used for control of Ordnance, Director Firing Gear, Ammunition Hoists, and other special purposes where positive control is essential.

A Continuously-Variable Chain-Driven Change-Speed Gear.

The P.I.V. (Positively Infinitely Variable) Chain Gear gives any desired speed variation up to six to one with a fully positive drive by means of an all-metal chain. The chain rides in the Vee formed between the opposed conical discs. These are formed with radial teeth, which are engaged by hardened steel laminations or 'slats,' held in the chain and capable of a small transverse movement enabling them to form teeth corresponding to those on the discs. An illustration of the chain showing the tooth formation is shown in fig. 46. The efficiency as shown by an N.P.L. test is 95 per cent. at full load. Gear-boxes, totally enclosed, with automatic lubrication, are made in five sizes up to 10 h.p. For full description, see 'The Engineer,' Aug. 27, 1926.

ADDENDUM.

Spur Gearing.

A report of recent researches conducted in America was presented to the American Gear Manufacturers' Association toward the end of 1930. The report deals with experimental work conducted on the Lewis testing machine to verify or modify the method by which the stress on gear teeth is determined.

Taking the Lewis formula, $W = ysfp$, and the stress formula, $S_v = S_o \left(\frac{600}{600 + V}\right)$ and, putting $yfp = K$, we have $W = K \left(\frac{600}{600 + V}\right) S_o$, which can be rewritten thus:

$$S_o = W \left(\frac{600 + V}{600K}\right) = \frac{1}{K}\left(W + W \frac{V}{600}\right).$$

The first item, W within the brackets, is the static load which can be applied to the gear, while the second item is that usually known as the increment load, which arises due to errors in tooth form, inaccuracy of tooth spacing, etc.

The equation shows the latter to be directly proportional to the static load W, a fact which in the light of these researches is erroneous in the case of high-speed gearing. The increment load depends upon inaccuracies in gear cutting, speed, and nature of material. The most common materials used seem to make the increment load practically independent of the static load. The former is apparently dependent upon the modulus of rigidity of the material used, since in the case of cast-iron gearing the increment load is more dependent on the applied load than is the case with steel gears. This is probably accounted for by the fact that the material with the lower modulus of rigidity is better able to absorb shock.

The increment loads given by the old formula are in many cases much in excess of the new values obtained in these researches, particularly in the case of the highly rigid materials such as the steels now employed. Complete data for calculating the increment load as determined by these new researches is not yet available.

SECTION XIX

PART IV

LINK MOTIONS.

(H. T. Davey, A.M.I.Mech.E.)

The Pantagraph.

This arrangement, fig. 1, is such that a point is constrained to copy to any desired scale the locus of another point. By this means reproductions are obtained. A common application of the pantagraph is in the engraving machine. Referring to fig. 1, AC, CP_1, BE, DE, are four levers,

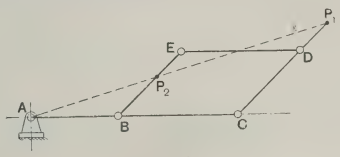

FIG. 1.

having pin joints at BCDE and forming a parallelogram, in which BE is parallel to CP_1 and DE is parallel to BC. The complete mechanism is pivoted to a bracket A. Points P_1 and P_2 are tracing points, P_2 being in link BE, so that A, P_2, and P_1 are in a common straight line. P_1 is guided over a figure to be reproduced, and P_2 traces a reproduction to any desired scale. P_2 can also be the guided point, and P_1 will then trace out the reproduction.

Link BC is kept constant and the length of AC is varied—*i.e.* ratio $\frac{AB}{AC}$ may be varied, and a reproduction to a desired scale be made.

BE is parallel to CD in all positions of the mechanism.

$\frac{AP_2}{AP_1} = \frac{AB}{AC}$ = constant. Hence the locus of P_1 will be similar to that of P_2.

See also p. 90.

Crosby Indicator Link Gear.

This is a multiplying arrangement in which the motion of the indicator piston is kept as small as possible to minimise friction and inertia errors. The actual motion of the piston is

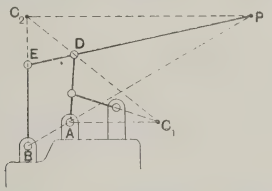

FIG. 2.

multiplied by a link motion (fig. 2). Links must be light to reduce friction and inertia, and P must move in a vertical path.

Points ABP are in the same straight line. C_1 and C_2 are the instantaneous centres of rotation

of links AD and EP respectively. The velocity ratio between P and A must be constant, P travelling in a straight line. Hence C_2P must be horizontal for all positions of the linkage, and the design must be arranged so that this is so, as nearly as possible.

Scott Russell Parallel Motion.

(1.)

In this motion, fig. 3, AB = AO = AC, and the angle BOC always a right angle. The link BC is constrained at point A by OA, which is fixed at O. OA is half the length of BC.

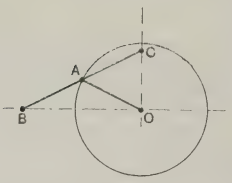

FIG. 3.

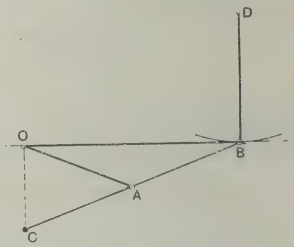

FIG. 4.

Point C moves along a straight line perpendicular to OB, and the locus of C is a reproduction of that of B. A small displacement of B causes a considerable movement of C as angle OAB approaches 180°.

(2.)

Point B, fig. 4, is not guided as in the Scott Russell linkage, but is controlled by a link BD, which in the normal position is perpendicular to OB. BD is relatively large, and hence the arc described by B is for a short length approximately a straight line. Hence C moves in a straight line.

Peaucellier Straight Line Motion.

This arrangement, fig. 5, is mathematically correct. It consists of seven pivoted links. Links

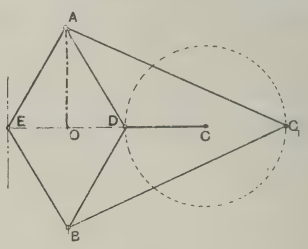

FIG. 5.

AC_1 and BC_1 are equal in length, and C, C_1 are fixed centres of rotation. Also AD = BD = BE = AE, and CD = CC_1.

Now

$$AC_1^2 = OC_1^2 + AO^2, \text{ and } AE^2 = EO^2 + AO^2;$$

therefore,

$$AC_1^2 - AE^2 = OC_1^2 - EO^2 = (OC_1 - EO)(OC_1 + EO) = DC_1.EC_1.$$

Thus since AC_1 and AE are both constant, $DC_1.EC_1$ is always constant, and therefore, since D lies in a circle, the locus of E must be a straight line, which is perpendicular to CC_1.

Kempe Straight Line Motion.

(A. B. and H. R. Kempe.)

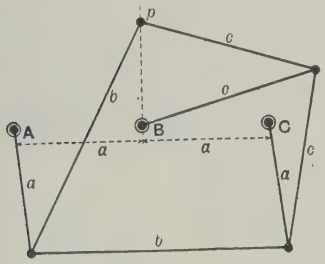

FIG. 6.

This, like the Peaucellier Straight Line Motion, is mathematically correct. The arrangement, fig. 6, is a combination of seven links, with three of the links pivoted at A, B, and C. The relative lengths of the links a, b, and c are such that

$$a : c :: c : b,$$

or,

$$c = \sqrt{ab}.$$

In the fig., a and b are in the proportion of 1 to 2, so that

$$c = \sqrt{1 \times 2} = \sqrt{2}.$$

With this arrangement the point p is constrained to move in an *accurately straight line traverse* away from B, towards B, or beyond B, the movement being perpendicular to AC.

So long as the value of c is such that

$$c = \sqrt{ab},$$

the proportionate value of a to b may be varied as desired, though it is not desirable to have this value very disproportionate, as although the straight traverse is still theoretically preserved, the arrangement becomes unstable from a practical point of view, through lack of *stiffness*.

Watt Link-Gear.

This is an approximate straight line motion. The arrangement, shown by fig. 7 in two forms, consists of two links AC, BD, which are pivoted at A and D, and connected together by a link BC. In the normal position, AC and BD are parallel, the connecting link being perpendicular to the links AC, BD.

A point P may be selected in the link BC, so that it moves in a straight line when small oscillations of AC and BD are made. Actually a point P in this link traces out a lemniscoid and only

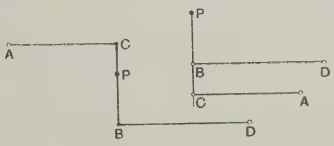

FIG. 7.

a small portion of its locus is a straight line. The required point P to give a straight line reproduction is found by making the lengths CP, PB, inversely proportional to the lengths of the levers.

The Watt link-gear is often combined with the pantagraph (see fig. 1), so as to provide two points having approximately linear motion, as in the beam engine, for example.

Quick Return Motion.

The link motion shown in fig. 8 is that commonly used in shaping machines in which the cutting stroke is made during the slower movement of the tool, while the return or non-cutting stroke is made more quickly. The cutting stroke is accomplished during the slower swing of the slotted link *l*—*i.e.* when the crank-pin *c* is moving in the upper arc of its path; the quick return stroke is made while the crank-pin moves in the lower arc of its path.

The ratio of the gear is equivalent to $\frac{\text{average time of cutting stroke}}{\text{average time of return stroke}}$.

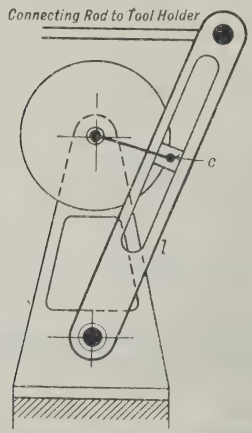

FIG. 8.

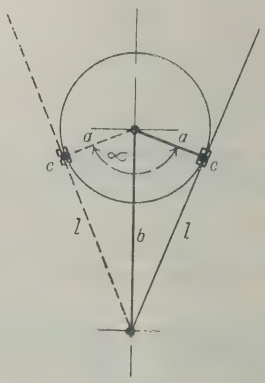

FIG. 9.

When the crank-arm a is at right angles to the slotted link l this link is then in its extreme position either to the left or right of its centre position. The cutting angle is therefore $360° - \alpha$, while the return angle is α (see fig. 9).

Hence the ratio of the gear $R_G = \frac{360° - \alpha}{\alpha}$.

Also, referring to fig. 9 : $a = b \cos \frac{\alpha}{2}$.

If R_G is known, then the lengths of the links can be determined from the given equations.

INDUSTRIAL STROBOSCOPES.

(A. J. Ashdown, Ltd., 119 Victoria Street, London, S.W. 1.)

'Stroboscope' is a general term appertaining to the science of motion study by interrupted vision. Its purpose is to provide a more intimate insight into the behaviour of mechanical and physical motions under conditions where theoretical considerations can sometimes be very misleading, owing to non-possession of all the factors which will govern the particular motion. In the last four years the use of stroboscopes has very considerably extended, and in practically every branch of industry it is used to confirm or modify features in mechanical design.

The principle on which the stroboscope works is that of retentivity of vision. The apparatus permits a succession of glimpses of the moving object to be received which, by this retentivity, blend into one continuous picture to the vision. It is obvious that as the object will frequently be moving at a high velocity it moves during the glimpse, and the latter must therefore be of

such shortness of duration that the object will have moved through but an infinitesimal distance; otherwise a 'blurring' or drawing out of the image will result.

The apparatus is so arranged that these glimpses can be given in exact synchronism with the moving object—in which case the object appears to be motionless—or it can be set at a speed slightly in excess of or less than that of the object, in which case the well-known 'slow-motion' study is permitted.

Stroboscopes are divided broadly into two divisions: in the first, the light illuminating the object is interrupted; in the second, the light remains continuous, and the line of vision itself is interrupted. Both methods are now in a very complete state of development. In the first form a neon-gas tube is used, and some forms of this apparatus are capable of giving amazing results. Such stroboscopes, however, necessitate the use of high-frequency currents of extremely high voltage discharged from a bank of condensers, this taking place between two electrodes

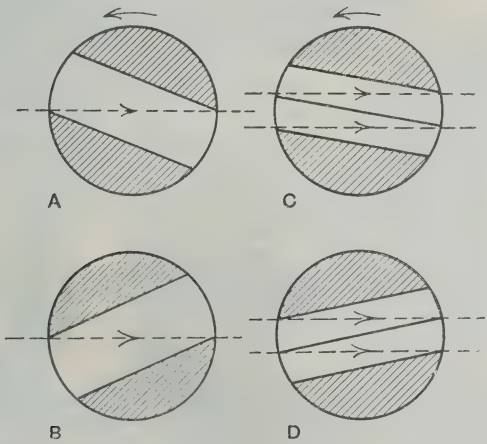

FIG. 10.

within the bulbs. As the heat capacity of the rarefied, inert gas is practically negligible, the tube lights up and darkens to all intents and purposes instantaneously as the current switches on and off. With this form another objection is that, in most cases, fixed contact has to be made with some part of the object to secure the necessary synchronism; also that for satisfactory observation all existing lighting must be obscured so that the full benefit of the timed flashes can be secured. It must be obvious, therefore, that the interrupted-vision type has here a very great advantage, for the reason that all the available normal lighting can be utilised, amplified when necessary by an ordinary continuous source of lighting. However, a mechanical shutter to operate with sufficient rapidity is an extremely difficult problem, and cannot be accomplished by any disc form of the Plateau type.

In 1925 the Ashdown Rotoscope was put on the market; its special feature lies in the shutter, or 'sight-gears' as they are called. In the simplest of these, known as the 'bladed' type, the vision slits are bladed, or 'compounded' as it is called, which results in the large field and ample lighting of a very wide slit being secured with the sharpness or 'definition' of an extremely narrow slit. The principal is shown in fig. 10. A second form is known as the 'heteroptic' shutter, which consists of two cylinders, one rotating within the other, and both revolving at extremely high velocities but at different speeds. By this means a 'phasing' takes place, and the requisite succession of glimpses takes place, each of which has a duration of less than one one-hundred-thousandth part of a second. So sharp and clear is the definition obtained, in fact, that it is possible to read from newspapers as they are coming off the printing-presses at a rate of 600 to 700 per minute.

This apparatus has a speed range in the standard types of from 100 to 40,000 per minute. Thus any object, with no matter what form of motion within this speed range (either rotary, reciprocating, or vibratory), can be intimately studied at an apparent speed of less than one-thousandth the actual.

A most important secondary function of the Ashdown Rotoscope is that it will ascertain, with considerable accuracy, the speed of any motion within the above range, and the extent of any speed variations taking place, without contact in any way with the object—*i.e.* at a safe distance.

BEARING PRESSURES—HEATING OF BEARINGS—BALL AND ROLLER BEARINGS

(Revised by Professor Dempster Smith, M.B.E., M.Sc., M.I.Mech.E.)

BEARING PRESSURES.*

Pressures on Bearings.

The following table shows the wide variation of pressure in bearings :—

	Lbs. per Sq. In.
Light and fast-running cotton spindle	2 to 5
Light shafting	80 to 100
Heavy shafting	300 to 600
Marine engine crank pins	600 to 900
Crosshead pins (horizontal engines)	1,200 to 1,300
Crank pins ,, ,,	800 to 950
Crank shaft (steam load) ,, ,,	100 to 150
,, ,, (combined load) ,, ,,	150 to 200
Second motion bearings ,, ,,	100 to 200
Crosshead slides ,, ,,	40 to 50
Intermediate piston rod slides ,, ,,	20 to 40
Main bearings (vertical high-speed engines)	200 to 300
Crank pins ,, ,,	400 to 550
Crosshead pins ,, ,,	1,000 to 1,200
Crosshead slippers ,, ,,	40 to 50
Eccentric straps ,, ,,	60 to 70
Crosshead pins (locomotive)	1,400 to 1,800
Crank pins ,,	1,000 to 1,500
Axle bearings (loco. engine and tender)	200 to 250
Railway carriage bearings	300 to 350
Babbitt metal on cast-iron slide	200 to 250

MAXIMUM SAFE PRESSURES ON BEARINGS.

Nature of Bearing.	Safe Load. Lbs. per Sq. In.
Ordinary bearings for shafting :—	
Wrought-iron on cast-iron	250
Wrought-iron on gunmetal	300
Mild steel on cast-iron	300
Mild steel on gunmetal	370
Mild steel on white metal	500
Cast-steel on gunmetal	600
Flywheel shaft	250

At unit pressures of 250 lbs. per sq. in. for cast-iron bearings, and 145 lbs. for bronze bearings, there is difficulty in keeping the boxes from seizing the shaft.

* For Bearing Metals, see METALLURGY, Section XL.

Professor W. C. Unwin carried out a series of experiments with Delta White Antifriction Metal, of which particulars are given. These tests show that this metal heats but little, even with high-bearing pressures :—

Mean Revolutions of Shaft per Minute	Mean Pressure per Square Inch of Journal Surface in lbs.	Mean Temperature in Deg. Fahr.	Mean Moment of Friction in lbs.-in.	Net Pressure on One Step in lbs.	Friction on One Step at Journal Surface in lbs.	Co-efficient of Friction

Heating of Bearings.

SIGNALS FOR INDICATING HEATING OF BEARINGS.

The double iodide of silver and mercury, $AgIHgI_2$, is a pale lemon-yellow powder at ordinary temperatures, and changes to a vivid carmine colour at about 90° to 100° C., the change in both directions being fairly sharp. The copper mercuric iodide, $Cu_2I_2 2HgI_2$, is a vivid scarlet-vermilion at ordinary temperatures, and at 60° to 70° C. it changes to a chocolate-brown. Both these compounds are adapted for use under suitable conditions, but a mixture of the two, consisting of 85 per cent. of the copper salt and 15 per cent. of the silver salt, is more sensitive and gives a greater colour range from vermilion to almost black, the transition being exceedingly sharp.

The compounds may be prepared in a variety of ways. A simple method of preparing the copper salt is by well triturating in a mortar 380 grms. of cuprous iodide with 910 grms. of mercuric iodide, sufficient water being added to form a paste. When thoroughly mixed, the mass is dried in the water-oven, and the dried mass ground to an impalpable powder. Another method is to dissolve the mercuric iodide in excess of potassium-iodide solution, and precipitate the double salt by the addition of copper-sulphate solution. The silver salt can be prepared in a similar manner by double precipitation. Whichever method is adopted the product should be well washed to eliminate soluble impurities, as these appear to retard the colour-change, as well as to affect its character.

To apply the mixture, convert it into a varnish paint or enamel, by incorporating the powder with a colourless varnish medium that will stand moderately high temperatures without softening. A good white-shellac spirit-varnish, such as is used on electrical machinery, has been found suitable for most occasions, but for high temperatures a medium such as is employed in the high-temperature aluminium paints used for steampipes, and which will resist temperatures up to 200° C., is preferable. About 100 grms. of compound to 70 c.c. of medium will be found a mixture of suitable consistence.

A convenient method of applying this heat-detector is first to paint a white circle or ring on the bearing or other place which it is desired to keep under observation, using a zinc-white paint. This white circle is applied to the journal or housing of the bearing, and the detector-paint is applied as a vivid red bull's-eye in the middle of this, thus forming a striking object which is visible from considerable distances. It must be applied to the block of metal as near as possible to the point at which the heat is likely to be generated. It is sometimes desirable to apply the paint to the shaft itself, just where the latter extends beyond the bearing-metal. A convenient method is to apply a broad band of white paint with a narrower band of the red detector paint in the middle. This red band in the middle of the white one is easily seen as the shaft rotates. In any case, after the paint is dry it should be protected with a coat of colourless oil-proof varnish, so that the surface may be occasionally wiped free from dust and dirt. The visibility of the paint against its white background is high, the bright scarlet colour being visible from long distances without effort, and the change at 60° to 70° C. to black is easily observed. It is generally easy to arrange matters so that the detector is placed in a position where it is visible almost without conscious effort; and experience has proved that a workman is easily trained to cast his eye occasionally on the detector, while he could not be depended upon to climb to the spot and feel the bearing on the remote chance of finding it heating. When the paint changes colour there is something wrong with the bearing, but generally speaking it will be found that the matter is taken in time, and that no damage is done, the bearing simply requiring cleaning and adjustment without serious stoppage and expense. (*H. T. Pinnock*, '*Journal of the Chemical Society.*')

BALL AND ROLLER BEARINGS.

(Contributed by John Goodman, M.Inst.C.E.)

BALL BEARINGS.

In the earliest cylindrical or radial bearings the balls bore on four points as shown at A, fig. 1,* and corresponding thrust bearings were made, as shown at F. It is impossible, under such conditions, to secure a pure rolling motion for the balls, so that grinding inevitably takes place.

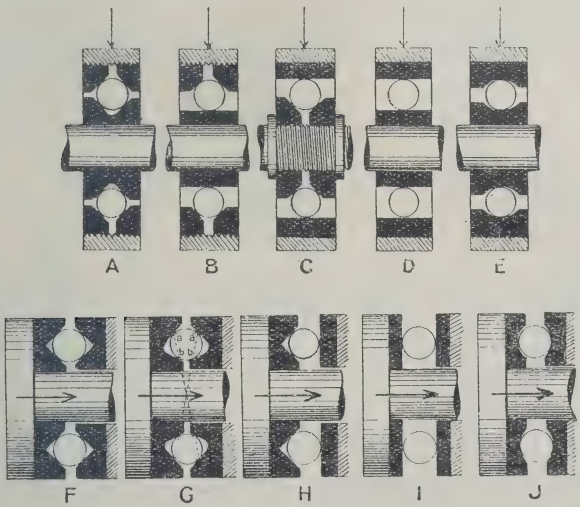

FIG. 1.

* Fig. 1 is reproduced from Professor Goodman's 'Mechanics applied to Engineering,' by the permission of the publishers, Messrs. Longmans, Green & Co.

The modification shown at G was then tried, but only with partial success. Three point bearings such as those shown at B, C and H, and also many others, were tried, but in every instance the balls grated and developed deep scratches after running for a short time; they were then abandoned for two-point bearings (the outcome of experiments by the writer), shown in D and I. The friction was found to be less, the bearing was cheaper to make, the balls had a true rolling motion, and, consequently, showed no signs of scratching, grinding, or wear; the bearings ran smoothly, and were in every respect a success. In general, a cage was used for keeping the balls in their relative positions, but in some instances it was found that it might be dispensed with. Other experimenters, notably Professor Stribeck, of Berlin, modified the two-point bearing by providing grooved ball races, as shown in E and J. Balls running in such races will support considerably greater loads than when running on plain surfaces which, of course, is a great advantage. The load that may be placed on a bearing of given dimensions, other things being equal, depends upon the relative radius of the groove and that of the balls, the smaller the difference between them the greater the load-carrying capacity; in modern bearings the radius of the groove is about 5 per cent. greater than the radius of the balls. The safe load also depends upon the number and the diameter of the balls, but it is, of course, useless to increase the diameter of the balls at the expense of the races, which must be sufficiently robust to retain their shape under load.

Radial Ball Bearings.

A considerable amount of thought and ingenuity has been expended on the problem of introducing the greatest possible number of balls into a radial bearing.

In the bearing D there is no difficulty in inserting the full number of balls, but in bearings which have grooved tracks as shown at E it is necessary, when assembling, to displace the one race relatively to the other, as shown in fig. 2, when the bearing can be filled to the extent of half the full number of balls *plus* one. The section through such a bearing is shown in fig. 3.

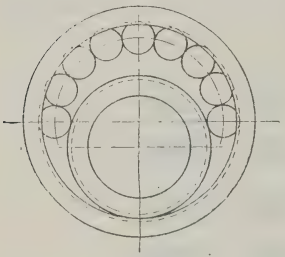

Fig. 2.

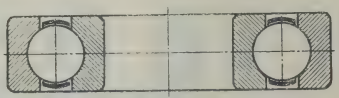

Fig. 3.

Extra balls can be inserted through transverse filling slots in the sides of the grooved tracks, the depth of which must be less than that of the groove, so that the slot does not extend to the middle of the track or in any way interfere with the pathway of the balls; but this condition is not so easily fulfilled as it may appear at first sight. The balls may be quite clear of the filling slot when the bearing is unloaded, but when it is loaded both the ball and the track are distorted to such an extent as to render it possible that the side of the track may be intersected by the filling slot; it is obvious that this is more liable to occur when the radius of the track closest approaches that of the balls. Thus on the one hand a small difference between the radius of the track and the ball is aimed at for the sake of increasing the safe load on the balls, and on the other a larger radius of track has to be used in order to prevent the balls from fouling the filling slot. Thus it is a matter of opinion as to whether the bearing provided with filling slots and a larger number of balls running in a wider track will actually carry a greater load than the bearing without such slots and with a closer fitting track with a smaller number of balls.

In order to overcome the difficulty of inserting the full number of balls, the 'Skefko' bearing is made with the outer ball track a portion of a sphere, the centre of which coincides with the centre of the shaft (fig. 4).* By this arrangement the outer race will swivel relatively to the inner (see fig. 5), when a full number double row of balls can be inserted.

* A filling slot materially reduces the capacity of the bearing to take end-thrust.

The swivelling property of the 'Skefko' bearing also has other advantages. If the housing shifts relatively to the shaft due to a lack of rigidity in the machine frame, or if the shaft itself is out of truth, the bearing will still run perfectly.

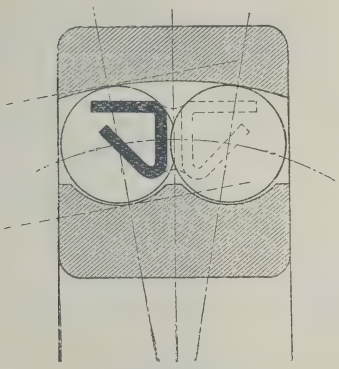

FIG. 4.

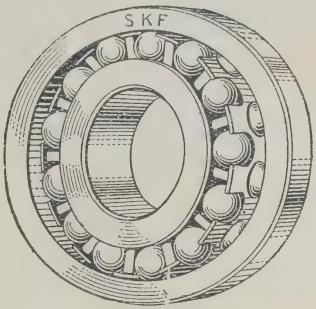

FIG. 5.

In fig. 6 is shown a 'Hoffmann' self-aligning outer race and shell and self-aligning end covers to accommodate errors in mounting. When a bearing is not completely filled with balls it is obvious that a cage must be used or the balls may crowd together and cause trouble. For moderate speeds a light sheet metal cage may be used, but for high speeds a more robust

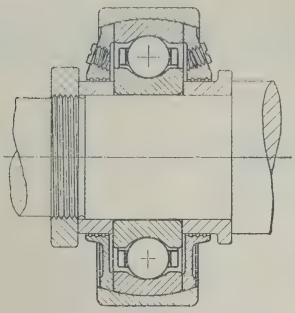

FIG. 6.

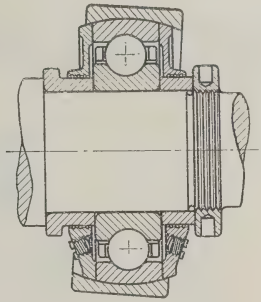

FIG. 7.

cage is necessary, accurately machined all over and fitting on the inner ball race ring to prevent the cage from running eccentrically. At very high speeds the centrifugal force on an eccentrically running cage becomes serious and is certain to give trouble. White metal and aluminium do not possess sufficient strength or hardness; steel, gun-metal, or bronze give the best results.

For long line shafts the 'Hoffmann' bearing, shown in fig. 8, is mounted in a housing slung on a rocking pin to accommodate expansion of the shafting. The inner race is clamped to the shaft by an adapter or split taper sleeve.

In fig. 9 is shown a bearing hanger for the same purpose by the Skefko Ball Bearing Co. Ltd.

When bearings are required for loads beyond the capacity of a standard ball journal bearing, it is usually cheaper and better practice to use a standard roller journal bearing; or several

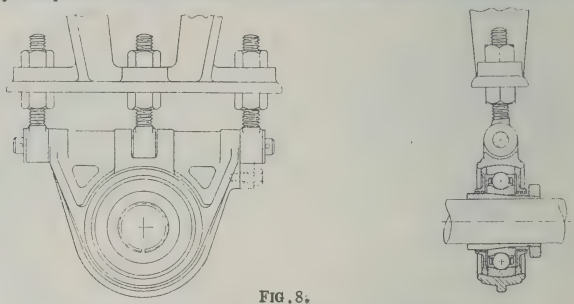

FIG. 8.

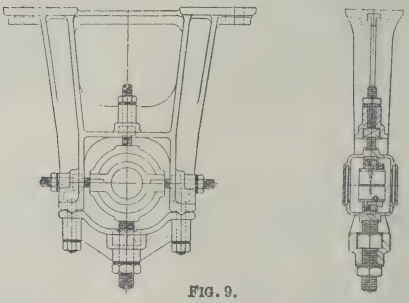

FIG. 9.

standard bearings can be mounted side by side, but there is a difficulty in ensuring that each bearing takes its fair share of the load. Goodman overcomes this difficulty by backing them with linoleum, vulcanised fibre, or hard wood. The housing is spherically mounted to allow it to adjust itself to any want of alignment (fig. 10).*

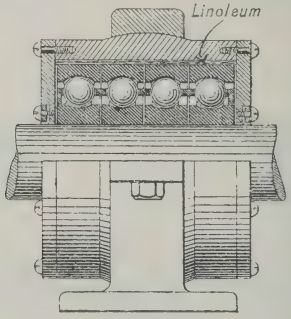

FIG. 10

* Fig. 10 is reproduced from a paper on 'Roller and Ball Bearings,' *Proceedings of the Institution of Civil Engineers*, vol. clxxxix, 1912, by the permission of the Council.

In all cases, even with single bearings, it is good practice to use a semi-hard backing when mounting ball and roller bearings. The backing acts as a cushion, thereby reducing noise, and it enables the outer ring to adjust itself to any slight lack of alignment.

Thrust Ball Bearings.

In thrust bearings there is no difficulty in getting in the full number of balls. A cage is always used. Radial bearings with grooved races will take a certain amount of end thrust, depending upon the radial load on the bearing. For numerical data on this question such a book as Macaulay's 'Ball and Roller Bearings' should be consulted.

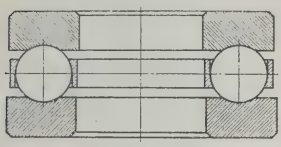

Fig. 11.

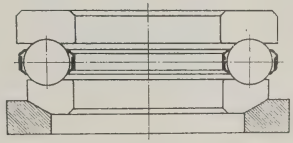

Fig. 12.

If the end thrust and radial load are large, two bearings should be used, the one to take the radial load and the other the end thrust.

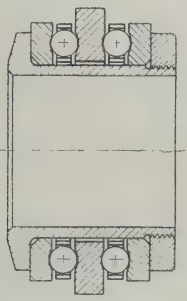

Fig. 13.

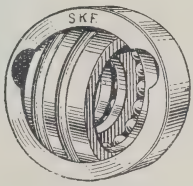

Fig. 14.

Fig. 11 shows a flat ring thrust bearing, and fig. 12 a thrust bearing with a spherical seat to accommodate errors in mounting.

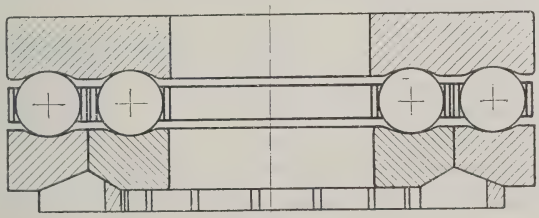

Fig. 15.

Fig. 13 shows a 'Hoffmann' double thrust ball bearing mounted on a sleeve, arranged to take thrust in either direction. The 'Skefko' bearing for the same purpose is shown in fig. 14.

For larger thrust loads multiple ring bearings are used mounted on a seating ring. The 'Hoffmann' bearing of this type, shown in fig. 15, is provided with an elastic seating ring to ensure the correct proportionate distribution of the load between both rows of balls; the 'Skefko' bearing in fig. 16.

Goodman mounts standard thrust rings on a linoleum backing, as shown in figs. 16 & 17.*

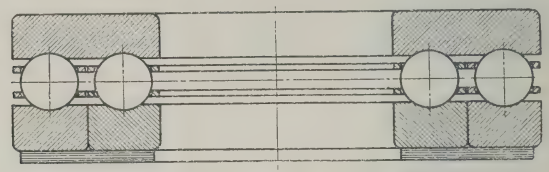

FIG. 16.

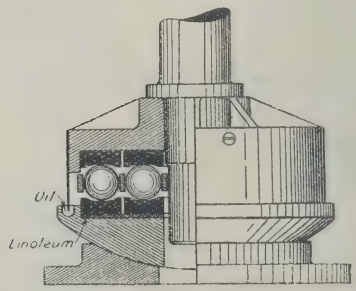

FIG. 17.

Permissible Loads on Ball Bearings.

The safe working load for a given bearing is much greater when the bearing is running at a low than at a high speed. The ruling factor as regards the working load for a ball bearing is the speed of rotation of the balls themselves; thus in the case of two shafts, A and B, each fitted with thrust bearings having the same number and diameter of balls, and both running at the same number of revolutions per minute, if the diameter of the ball path in A were greater than in B, the safe working load would be greater for shaft B than for A.

Let P = The maximum permissible working load in pounds;

d = The diameter of the ball in inches;

D = The diameter of the ball path in inches;

n = The number of revolutions per minute of the shaft;

k = A constant depending upon the form of bearing;

c = A constant;

m = The number of balls in the bearing;

x = A coefficient depending upon the revolutions per minute of the shaft.

Stribeck's formula for radial ball bearings is:—

$$P = 12{\cdot}8\ x\ m\ d^2$$

* Fig. 17 is reproduced from a paper on 'Roller and Ball Bearings,' *Proceedings of the Institution of Civil Engineers*, vol. clxxxix, 1912, by the permission of the Council.

where x has the following values :—

n 0	10	150	300	500	1,000	1,200
x 48·4	36·3	29·04	24·2	20·9	15·62	14·96
n 1,500	2,000	2,500	3,000	4,000	5,000	10,000
x 13·64	12·1	10·56	9·68	8·58	7·7	5·06

Goodman's formula for ball bearings is :—

$$P = \frac{k\ m\ d^2}{nD + cd},$$

where k and c have the following values :—

Type of Bearing.		k	c
Radial.	Flat (i.e. not grooved) races	1,000,000	2,000
	Hollow races of ordinary quality	2,000,000	2,000
	Hollow races of best quality	2,500,000	2,000
Thrust.	Flat (i.e. not grooved) races	500,000	200
	Hollow races of ordinary quality	1,000,000	200
	Hollow races of best quality	1,250,000	200

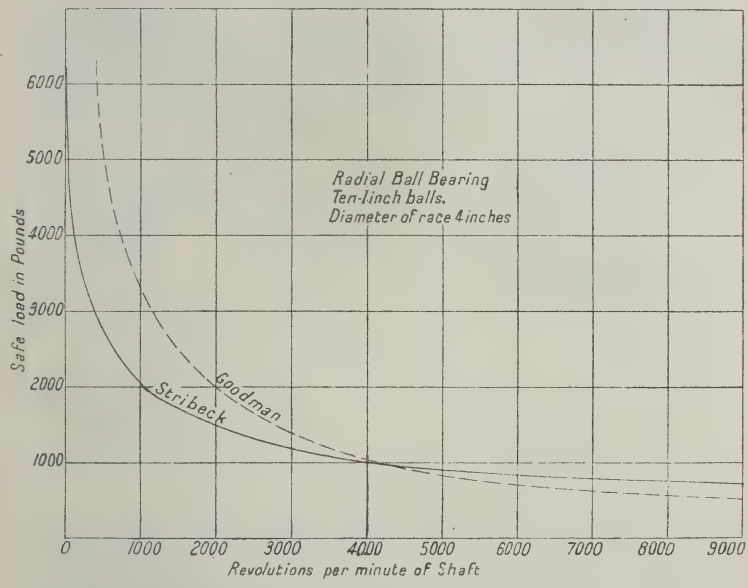

FIG. 18.

A comparison of the results obtained by the two formulæ is shown in fig. 18.

Load tables based on these or similar formulæ are published by most manufacturers. But in all cases other factors should be taken into account, such as the number of hours per day the bearing is likely to run, whether a steady or a fluctuating load, and whether it will be possible to keep it free from dirt, dust, and damp. When bearings are required for special conditions of running it is advisable to consult the manufacturers.

In the 'Skefko' bearing the races must be regarded as flat, but since there are at least twice as many balls in this type of bearing as in other bearings of the same external dimensions, the theoretical load carrying capacity is the same. It is claimed that this bearing will work satisfactorily with a small amount of lateral thrust.

Advantages and Disadvantages of Ball Bearings.

Advantages.

The friction is usually less than one-tenth of that encountered in ordinary bearings as commonly lubricated.

The friction at starting is no greater than when running.

The friction does not increase with the speed.

They require an extremely small amount of oil, the cost of which is negligible.

They occupy much less lateral space on the shaft than an ordinary bearing.

If the bearing is properly treated the wear is extremely small.

Disadvantages.

The first cost is usually greater than that of an ordinary bearing, but this is not invariably the case.

If overloaded, or if lubricated with unsuitable oil the balls pit and peel, and then they make a great deal of noise, especially at high speeds.

They require extreme care in fitting on to the shaft and in the housing.

Power Saving and Reduction of Starting Effort.

The power saving amounts to at least 90 per cent. of the loss due to friction of the best plain bearings, whilst the reduction of starting effort of no less than 99 per cent. means that the acceleration is more rapid, which is of particular importance in machinery where frequent stops and starts are essential. Further, the reserve of power usually required for starting machinery is unnecessary, and the size of the power unit can therefore be reduced.

The enormous saving in power, and still more remarkable reduction in starting effort, are illustrated by a test carried out by the National Physical Laboratory, the results of which are given in the following table:—

	Standard Plain Hanger.		'Hoffmann' Ball-Bearing Hanger (Patent).
	With Needle Lubricator.	With Oil Ring Lubricator.	
Starting effort.	830 in.-lbs.	770 in.-lbs.	0·9 in.-lbs.
Revs. per Minute.	Coefficient of Friction.		
80	0·014	0·015	0·0013
130	0·015	0·014	0·0014
250	0·016	0·013	0·0015
500	0·017	0·012	0·0016

Roller Bearings.

For heavy loads, particularly where the bearing is subjected to severe shocks, a roller bearing should be used in preference to a ball journal bearing.

The development of the roller bearing has been more difficult and consequently slower than the ball bearing owing to the tendency of the rollers to creep axially, the resultant end-thrust causing friction and consequent wear in the cage and rollers. This creep is invariably caused by

inaccuracy of the tracks and rollers; the smallest error along the length of these alters the relative peripheral speed and destroys pure rolling motion.

Four distinct types of roller bearings have been developed :—

(1) With cylindrical rollers in which the length is considerably greater than the diameter.
(2) With taper roller.
(3) With cylindrical rollers in which the length is equal to the diameter.
(4) With slightly barrelled rollers in which the length is equal to the diameter.

Bearing in mind the basic fact that 'Friction causes Wear,' the following table of coefficients of friction obtained experimentally by Professor Goodman (*Proc. Inst. Civil Engineers*, vol. clxxxix.) affords a sound method of comparison of the merits of the various types, and it will be seen that bearings with short cylindrical rollers are now made combining the efficiency of ball bearings with greatly increased load capacity :—

Type of bearing.	Ball.	Short Cylindrical Roller. III.	Taper Roller. II.	Long Cylindrical Solid Roller I.	Long Cylindrical Flexible Roller I.
Coefficient of friction	0·0010 0·0015	0·0010 0·0015	0·0020 0·0040	0·0030 0·0100	0·0040 0·0070

(1) *Long cylindrical roller bearing.*—This type of bearing has not proved satisfactory for arduous duty on account of the tendency of the rollers to 'skew.' The difficulty of manufacturing the rollers accurately as regards diameter and parallelism is obviously increased in proportion to the length, and the superimposed bending stresses caused by 'skew' also increase proportionately.

In the 'Hyatt' roller bearing the solid roller is replaced by right- and left-hand helical springs arranged alternately; it is claimed that 'skewing' difficulties are obviated by the flexibility of the rollers.

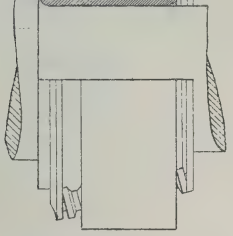

FIG. 19.

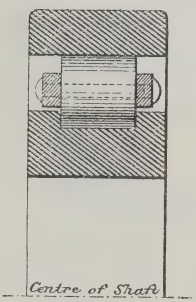

FIG. 20.

(2) *Taper roller bearing.*—Several makes of this type of bearing are now on the market, and it is claimed as advantages that the bearing will support both journal and thrust loads, and can be adjusted to take up wear.

On account of its design the bearing cannot be used singly except where there is a constant end-thrust in one direction.

While this type of bearing is adjustable when new and unworn, it should not be forgotten that under journal load only one half of the stationary race is loaded, and any wear in the track of this race will make it oval, whilst the revolving race and rollers may wear evenly and remain round.

Adjustment subsequent to wear is therefore analogous to forcing a round plug into an oval hole. One of the most successful bearings of this type is the Timken (see fig. 19); it is largely used for motor-car work.

(3) *Short cylindrical roller bearing.*—This type of bearing, fig. 20, was originated and developed in England by the Hoffmann Manufacturing Co., but is now made by many firms. The rollers are solid and have a length equal to their diameter. They are accurately finished on diameter to the same limits as balls, viz. plus and minus 0·0001 ins., and the ends are ground perfectly square. The extreme accuracy of these rollers is illustrated by the fact that they are supplied for use as gauges under a National Physical Laboratory Certificate of Accuracy.

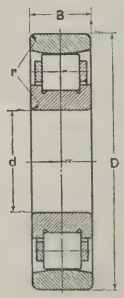

FIG. 21.—Cylindrical Roller Bearing, with convex outer race.

To guide the rollers, the inner race is provided with two lips to form a channel-shape track which, in conjunction with the accuracy with which the tracks and rollers are produced, effectually prevents any tendency to 'skew.' The outer race is a plain annular ring, and the rollers are separated by a cage of solid yellow anti-friction alloy metal.

With these bearings contact is obtained with both tracks along the whole length of the roller, from 70 to 130 per cent., and this 'line contact' gives a load capacity greater than that of a ball bearing of similar size, according to the conditions and nature of the load. The bearings are made with the same external dimensions (bore, outside diameter, and width) as ball journal bearings, and are interchangeable with them with only slight alterations in the mounting.

As the outer race has a plain cylindrical track, the bearing cannot take end-thrust of any sort, and to prevent its slipping sideways off the rollers, the outer race must be definitely clamped endways. This is a definite advantage where a roller bearing is mounted in conjunction with a

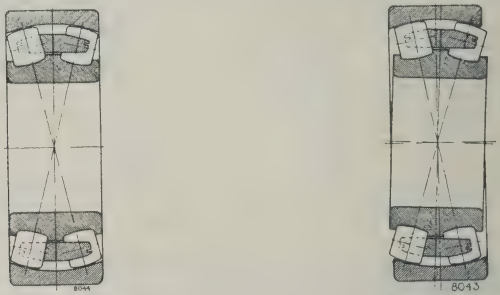

FIG. 22.—Double-row Self-aligning Roller Bearing.

ball bearing, and the outer races revolve, as both can be made an interference fit in the housing to prevent creep. Apart from this, the bearings should be mounted exactly similar to ball bearings.

The Skefko Ball Bearing Co. Ltd. make the outer race slightly convex in order to allow of a small

angular movement of the inner race relative to the outer, which has proved to be very successful in practice in cases in which there is a difficulty in maintaining an exact alignment between the shaft and housing (see fig. 21), but of course it will not take any end-thrust. Where end-thrust has to be dealt with in addition to radial load the bearing shown in fig. 22 is used. It has been

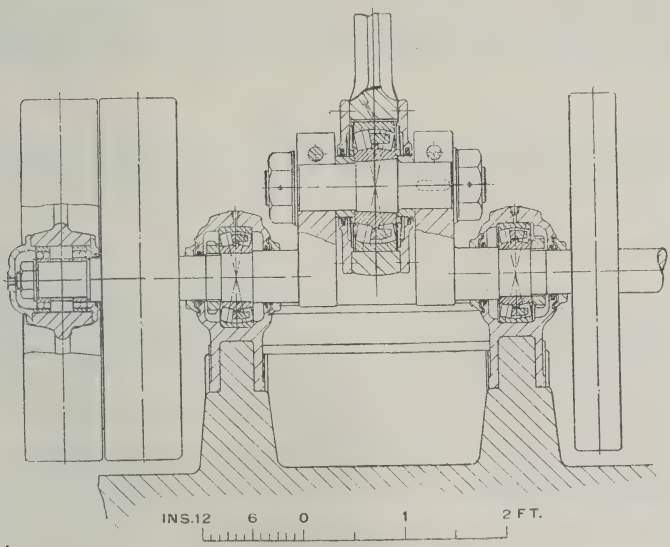

FIG. 23.

successfully used for heavy duty such as railway axle-boxes, trams, crushers, calenders, etc. On account of its construction it is able to negotiate thrust load in either direction simultaneously with radial load. This bearing can deal with a radial load of about 100 per cent. greater than a ball bearing of equivalent dimensions, and has been applied to a large number of passenger coaches where the speeds attained have been between 60 and 70 m.p.h.

ANTI-FRICTION BEARINGS FOR LOG FRAME-SAWS.*

Log frame-saws of the modern type have several saw-blades in series, mounted in a suitable frame made to slide up and down within the main frame of the machine by means of a crank and connecting rod. The type which is of particular interest here is the single-crank type, and fig. 23 illustrates a bearing arrangement which has been found effective.

The size of the crank-pin bearing, which is of the spherical double-row roller type, is as follows:

Bore, tapering, 140 mm. diameter at the smallest end;
Outside diameter, 380 mm.;
Width, 120 mm.

The connecting-rod is of wrought nickel steel, and the thickness of the material of the big-end housing varies between 30 to 50 mm. The crank radius is 250 mm. (approximately 10 ins.). If the width of the saw-frame is between 500 and 600 mm., its weight, complete with blades and accessories will be about 615 lbs., and the weight of the connecting-rod complete, including the outer ring of the roller-bearing, will be about 485 lbs. When the frame is running at a speed of

* J. B. Dahlerus, *Proc. Inst. Mech. Eng.*, 1925.

350 r.p.m., this being the highest speed attained so far, the maximum acceleration force on the crank-pin bearing will be about 37,600 lbs., or approximately 16¾ tons.

In calculating the maximum load coming on the bearing, the force required for sawing should also be added. This amounts normally to about 900 lbs. The calculated load is not, of course, constant, but varies intermittently throughout every revolution.

With a bearing of the dimensions given in this particular instance, the factor of safety is approximately two over the published figures, and has been found to meet the conditions admirably. The service on these machines is practically continuous day and night, so that the requirements in respect of durability and safety in operation are very severe.

General Applications.

Other machines where these bearings have been successfully applied include: ball mills; tube mills; pulp beaters for paper making; pulverizers; disintegrators; chocolate refining rolls; an alternator of 2,500 kw. at 1,000 r.p.m.; 3-bearing rotary converters; road wheels of motor buses; cross rolls in steel plant.

Mounting Ball and Roller Bearings.

The revolving race of a ball or roller journal bearing must be made an interference fit on its seating to prevent creep or slow rotation of the race relative to the shaft or housing, and it is advisable to clamp this race firmly endways. The stationary race should be allowed just sufficient clearance on its seat to permit it to take up its correct position endways relative to the revolving race, and sufficient end clearance should be arranged for to prevent the stationary race coming in contact with a shoulder and thus putting a permanent side-thrust on the bearing.

The writer of this article considers that the stationary race should be mounted with a soft backing such as linoleum, a hard wood ring, or hard fibre in order to reduce noise and to allow of a small movement if the housing gets out of alignment.

In obtaining the necessary fits it is essential that the seatings and abutments of the housing and shaft be perfectly round and true. The hardened steel races have a comparatively thin section, and should be regarded purely as tracks for the balls, as they will conform readily to inaccuracies of their seatings.

The use of set screws, keys, or similar devices for fixing the races and preventing creep cannot be too strongly deprecated, as they readily distort the races, causing overloading of the bearings. In any case, it will be found these are of very little use as they shear or fret away rapidly.

Where there is no definite end-thrust the shaft may be located endways by clamping the stationary race of one bearing only in a solidly connected length of shaft. The most lightly loaded bearing should be selected for this purpose.

The revolving race of a ball thrust bearing should be made a push fit on the shaft, and it is essential that the shoulder against which it abuts is perfectly smooth and square. It should be of such diameter as to extend at least half-way across the track of the race to adequately support this and prevent deflection under load. The stationary race must be held concentric, and where it is not possible to ensure a perfectly square seating, a self-aligning bearing should be used.

It is essential that a ball thrust bearing be not called on to take any journal load whatsoever, and a journal bearing of some kind must be mounted immediately alongside to ensure that the two ball races are held concentric. A ball or roller bearing is, of course, to be recommended for this, as it will not wear slack and allow the shaft to drop out of concentricity with the housing.

For high speeds it is important to keep the pitch diameter of the races and the size of the balls as low as possible, and where thrust bearings are required for speeds above those listed by manufacturers, it is advisable to consult the makers.

Split housings should as a general rule be avoided, and it is generally found an advantage to make the housings in the form of plain, eye-bored castings, and fit loose end covers for protection and retention of lubricant.

Perhaps the most frequent cause of failure of a ball bearing is lack of protection against dirt and water. The highly polished surfaces of the balls and races render them peculiarly liable to corrosion and rust. Grit or dirt in a bearing is crushed between the balls and tracks, forming an abrasive compound which causes rapid wear.

For ordinary conditions it is sufficient to make the protecting end cover as wide as possible where it meets the shaft, and to bore it out with a diametric clearance of about 0·010 in. A series of annular grooves should be turned in the bore, which will become filled with grease and form grease seals.

For special conditions, where there is excessive dust or moisture present, extra protection is necessary, and throwers should be fitted on the shaft overhanging the end covers so that the rotation of the thrower will tend to throw off the dirt or water and prevent its having direct access to the aperture between the end cover and the shaft.

Where it is not possible to obtain accurate alignment between two housings, self-aligning bearings should be used, but it should be noted that these can only swivel about one centre, and will not accommodate actual lateral displacement errors, so that where there are more than two bearings per shaft the self-aligning feature is of use only to accommodate want of squareness of the housing. For self-alignment of two or more bearings mounted in a rigid housing it is essential that all the bearings swivel about one point.

Manufacture of Ball and Roller Bearings.

The success of ball and roller bearings depends upon extreme accuracy of manufacture and fitting; also on the quality of the material. All must be of the very best. The manufacture of such bearings requires great skill and special plant, hence it is the height of folly for firms not equipped for such work to attempt to make their own bearings.

Some makers favour special low-carbon steel, deeply carburised on the tracks only; others prefer high-carbon chrome alloy steel. Since highly satisfactory bearings are turned out from both kinds of steel, it is impossible to say which is the better.

For special purposes, such as to resist corrosion or chemical action, stainless steel is sometimes used, but as regards load-carrying capacity it is not equal to the standard materials.

After rough finishing, both balls and races are carefully heat treated and then finished by grinding and polishing to a very high degree of accuracy. Balls are produced to guaranteed limits, both as to diameter and sphericity, of + or — 0·0001 in. The ball tracks also have to be finished to the same degree of accuracy. The bores and outside diameters of the races of best quality bearings have a tolerance of only 0·0005 in., from which it will be evident that the bearings are to a very large extent interchangeable.

The reason why extreme degrees of accuracy in workmanship are necessary for ball and roller bearings will be apparent when it is remembered that the approach of two surfaces when separated by a ball is extremely small for safe loads, hence if there be only very small hills on either the balls or tracks the increase of load as the ball passes is very severe. Articles dealing with this question will be found in *Engineering*, Aug. 3 and 24, 1923, also June 19, 1925.

When under load the balls and tracks are deformed until there is a measurable but very small area of contact, the stresses on this area are consequently very high, which are repeated many millions of times during the life of the bearing.

Lubrication of Ball and Roller Bearings.

In a ball or roller bearing the intensity of pressure between the rolling elements and the track is such as to entirely squeeze out every trace of lubricant, and actual metal-to-metal contact occurs. This does not mean that a ball or roller bearing will run satisfactorily without any lubricant, which is necessary to lubricate the cage containing the balls or rollers, and to protect the tracks and rolling elements from corrosion. In a high-class bearing the greatest care is taken in obtaining a surface as free from imperfections and scratches as it is possible to produce commercially. This extreme care is necessary to obtain durability, a low coefficient of friction, and silence in running. Unfortunately, surfaces of this character are particularly susceptible to corrosion, and it is essential, therefore, that the lubricant be free from all solid impurities or free acid, and the free alkali should not exceed 0·1 per cent. Lubricants with an animal or vegetable base are all liable to develop free acid over a period and are therefore unsuitable.

For normal conditions a pure mineral grease, perfectly neutral, and of a consistency rather greater than that of vaseline, is the most suitable lubricant for ball and roller bearings. It must not readily absorb moisture, nor contain solidifying matter such as French chalk, graphite, etc., which would act as a lapping compound and cause rapid wear and deterioration of the bearing. At high speeds the lubricant used in a bearing is subjected to severe churning action, and unless a good quality grease be used, it will be found there is a tendency for the grease to disintegrate, the oil running out of the bearing, leaving a hard, gummy residue which clogs and finally breaks up the cage and thus destroys the bearing.

In exceptional cases where the bearing is exposed to an abnormally high temperature, grease with a high melting-point should be used. This is obtainable suitable for use up to a temperature of 300° F. Its consistency, however, is very stiff at normal temperatures, and it should therefore not be used where there is no external heat.

If arrangements can be made to prevent leakage, oil may be used for lubrication, and, indeed, at high speeds is preferable to grease. It has, however, the disadvantage that where the bearing is likely to remain stationary for any length of time the oil will drain away from the upper surfaces, leaving them exposed to the corrosive action of the atmosphere.

Provision must be made for replenishing the lubricant. This, however, is only necessary at long intervals, which vary according to the conditions under which the bearing is running. The grease may be inserted by a Stauffer or other lubricator, or by means of a grease pump, but it is of the utmost importance that the grease used, and the hole through which the grease is inserted, are perfectly clean; the latter should be kept plugged. It cannot be over-emphasised that the best of bearings can be ruined in a few days by the action of dirt or water.

SECTION XX

PART II

LUBRICATING OILS, LUBRICATION, AND LUBRICATORS.

LUBRICATING OILS.

(Contributed by Harold Moore, M.Sc.Tech., M.Inst. Pet. Tech., F.C.S., A.I.M.E., and R. B. Hobson, A.M.C.T., A.M.I. Pet. Tech.)

At the present time most machinery is lubricated either by means of mineral oils or by mixtures containing a large proportion of mineral oil with a small amount of either animal or vegetable oil added. The mineral oils used are almost entirely derived from petroleum, but a certain amount of low-viscosity oils, such as spindle oils, are prepared from shale oil, and certain tar and lignite products are used for grease manufacturing. Where coal tar and lignite are available in quantity, coal tar and lignite products are used as substitutes for petroleum products. As a general rule the petroleum product is the superior article, and it is only for exceptional purposes that coal tar or lignite products are found to possess equal values with the petroleum oils. For grease-making, however, anthracene oil, a heavy distillate of coal tar, is used to a considerable extent in this country.

Lubricating oils may be divided into three classes: (1) the straight run mineral oils, which are certain fractions obtained by the distillation of petroleum; (2) certain blended oils, which are mineral oils prepared by the mixture of two or more different varieties of mineral oil; and (3) compounded oils, which contain mixtures of mineral oil, together with either animal or vegetable oil.

Lubricating oils of very high viscosity are prepared by distilling off a large portion of the oil, and then utilising the residue as lubricant. The residues are usually dark, and are known as 'dark steam refined cylinder stock.' For very high-class oils of high viscosity it is necessary to remove a certain amount of the bituminous content of these residues, and this is effected by filtering the cylinder stock through fuller's earth, bauxite, or adsorbent clays, when the bituminous bodies are absorbed and the black, opaque cylinder stock is converted into 'filtered cylinder stock,' usually of a greenish colour and semi-transparent. Such cylinder stocks are generally mixed with the distillate to give blended oils of any desired viscosity.

The distillates used for lubrication are generally refined, either by treatment with sulphuric acid or by filtration through fuller's earth, bauxite, or clay. The characters of the lubricants obtained from the crude oil, though to some extent affected by the treatment to which the oils have been subjected, is mainly dependent upon the nature of the oil which is used in the first place for the preparation of the lubricant.

The most important properties by the estimation of which the valuation of lubricating oils is effected, are the 'specific gravity,' 'flash-point,' and 'viscosity,' and in special cases it is also necessary to determine the coke content, demulsification properties, acidity, content of saponifiable oil, and a large number of minor tests. The main importance of the specific gravity is its value as denoting the base of an oil. The 'open flash-point' is determined by heating the oil in an open cup, observing the temperature, whilst a small flame is periodically brought to bear upon the surface of the oil, the open flash-point being that temperature at which a small sheet of flame flickers over the surface of the oil and immediately goes out. If the oil is heated to a higher temperature after the observation of the open flash-point, it will eventually reach a temperature at which sufficient inflammable vapour is generated to maintain a flame on the surface of the oil. This temperature is known as the 'burning-point' or 'fire-test.' Special instruments have been devised for the determination of flash-points, in which the oil is enclosed in a small cylindrical vessel, so that the vapour is not liable to be affected by currents of air. The results given by such instruments are called 'closed flash-point' tests. The Abel instrument consists of a vessel surrounded by a water-jacket to ensure gradual increase in temperature, and is designed for the testing of kerosene (lamp oil), the flash-point of which is required by governmental regulation to be above 73° F. by the Abel test. As the water-jacketed instrument is

unsuitable for testing flash-points at high temperatures, it is usual to employ either the Gray or the Pensky-Marten instrument for the testing of lubricants. Both of these instruments are very similar to the Abel apparatus, except in that a cast-iron jacket is employed in place of the water jacket, and that stirring arrangements are provided to allow of the agitation of the oil whilst heat is being applied. In the Gray instrument a bevel-driven paddle is used, whilst the Pensky-Marten has a paddle driven by a flexible shaft.

The property of viscosity is the resistance to motion, or, in common terms, the 'thickness' of the oil. As the viscosity varies according to temperature, it is necessary that a viscosity should be determined at some fixed temperature, in this country usually at 70°, 100°, 140°, 200°, or 212° F. As the rate of change in viscosity with increase of temperature varies with different types of oil, it is often necessary to plot a curve obtained by the viscosity of oils at various temperatures. The instruments usually used for measuring this property are the Redwood, Engler, Saybolt, and Barbet viscometers. The results of determinations made on these instruments are quite different, but the principle on which they work is very much the same in each case. It consists in allowing a quantity of oil to fall through a jet or tube, and in measuring either the time taken for a fixed quantity to pass through the instrument, or in measuring the quantity passed in a fixed time. The Redwood instrument is used in this country; the Engler is very extensively used on the Continent; the Saybolt is the standard American instrument; whilst the Barbet is generally used in France.

During recent years it has been frequently suggested that measurements of viscosity should be made in absolute units instead of in arbitrary units obtained in the various commercial testing appliances. The absolute unit of viscosity is the amount of force in dynes required to move a unit area of plane surface with unit speed relative to another plane surface, from which it is separated by a layer of lubricant of unit thickness. It is usual to employ C.G.S. units, and the result is obtained in dynes per square centimetre per second. This unit has been named the 'poise.' As the absolute unit is a comparatively large unit of measurement, and would be inconvenient for commercial use, it is probable that, if absolute viscosity measurements came into general use, the unit taken would be the 'centipoise,' or one-hundredth part of the absolute unit.

Mineral oils possessing similar viscosities at any particular temperature may not possess similar viscosities at a higher or at a lower temperature, the rate of fall in viscosity with increase in temperature being dependent upon the chemical nature of the base oil. For example, a paraffin base oil does not show nearly such a rapid fall in viscosity with increase in temperature as do the asphaltic and naphthenic base oils, and to compare the viscosity of oils it is really necessary to prepare a curve by plotting the viscosity against the temperature.

Though these three tests are the ones most commonly used in commerce, it is necessary to employ a large number of other tests for various particular purposes. For example, oils required for service on internal combustion engines should be tested by the coke test, to measure their liability to produce carbon in the engine. Oils required for use in turbines should be tested to ensure that they will readily separate from water without forming an emulsion. It is also necessary to ensure that the oils are free from mineral acids, and that they do not contain excessive quantities of organic acids. When compounded oils are under examination, it is necessary to determine how much of the saponifiable oil is present. It may also be necessary to test for inorganic matter by the determination of the ash content, or for water, or for mechanical impurities.

In addition to the properties mentioned above, there is the property of 'oiliness,' on which subject a great deal of research has been conducted during the last few years. This is undoubtedly a surface tension effect, and is the property of maintaining a film when subjected to pressure between two plane surfaces. This is a property which cannot be readily measured, but its influence is well known. Certain of the saponifiable oils, that is to say, animal and vegetable oils, are much more satisfactory as regards this property than are mineral oils, and it is frequently observed that when a saponifiable oil or a compounded oil is employed for any particular purpose it is possible to use a product of lower viscosity than if a straight mineral oil were being used for the same purpose. The asphaltic and naphthenic oils are slightly superior to the paraffin base oils as regards this property.

In drafting specifications for the supply of lubricants for any particular purpose, it is essential that note should be taken of the nature of the mineral oil employed as a base. It is quite insufficient to simply specify the usual properties of gravity, flash-point, and viscosity.

The colour of a lubricant, which denotes the degree to which it has been refined, is a matter of the greatest importance. Clear oils are preferable to turbid oils, and, as a general rule, oils of light colour are more valuable than darker oils.

Owing to the use of different standard instruments for the determination of the viscosities of oils, it is sometimes necessary to be able to convert values given in one standard into the corresponding values in another standard. The three tables, p. 1103, serve for the conversion of values between the Redwood, Engler, and Saybolt systems.

Viscosity in C.G.S. units $= 0{\cdot}00353 \left(3{\cdot}6 \text{ Red.} - \frac{\delta^2}{\text{Red.}}\right)$, approximately, where 'Red.' is the Redwood value, and δ is the density. *(H. R. K.)*

ACTION OF OIL ON METALS.

From experiments with common metals immersed in various oils for twelve months at normal atmospheric temperatures, the following results were obtained :—

Class of Oil.	Not affected.	Slightly affected.	Moderately affected.	Much affected.
Mineral lubricating	Copper, Zinc	Brass	—	Lead
Olive	—	Tin	Lead	Copper, Brass
Rape	Brass, Tin	Iron	—	Copper
Tallow	—	Tin	Iron	Copper
Lard	—	Zinc	Lead	Copper
Cottonseed	—	Lead	—	Tin
Sperm	—	Brass, Copper	Lead	Zinc
Whale	Tin	Brass	—	Lead
Seal	—	Brass	Iron	Copper

As fatty oils have a destructive effect upon metals at high temperatures in the presence of moisture, lubricants compounded of such oils and of hydro-carbon mineral oils, although serviceable for internal combustion engines, are not desirable for the internal lubrication of steam engines. *(Mechanical World Year Book.)*

The oil shall be a *Straight Mineral Oil.*

Method of testing : Inst. Pet. Tech. No tolerances allowed.

See also B.E.S.A. Spec. No. 210–1924.

* Issued by Diesel Engine Users' Association.

Simple Tests for Lubricating Oil.

Colour.—A good oil, before use, will appear of a clear colour, and will not separate into layers of different shades, or deposit sediment after being allowed to stand for a few days. It will not rust or corrode in any way any pieces of ordinary polished tool steel suspended in it.

Emulsion.—When mixed with warm water and shaken in a bottle the oil will soon separate entirely from the water and show no soapy emulsion. The test does not apply to marine engine oil nor to black cylinder stock oils which are blended, for obvious reasons, to produce this very emulsion.

Wax Content.—At ordinary temperatures it is a difficult matter to decide whether wax, either in the form of solid paraffin or some other substance, is or is not present. The readiest test is to cool the oil with ice, when the wax will have a tendency to separate out, and so cause the oil to appear cloudy.

Filtration of Oil.

When oil is properly filtered it can be used indefinitely without losing any of its lubricating qualities.

Recovery of Lubricating Oil.*

Settlement and Filtration Method.

Fig. 1 shows a waste oil filter made by Messrs. A. C. Wells & Co.; these filters consist of three compartments, any of which can be readily removed from the other to facilitate cleaning.

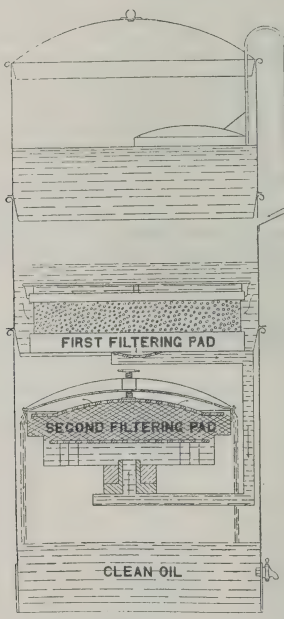

Fig. 1.

The top chamber receives the dirty oil, which after admission is allowed to settle for about a day, the time varying with the degree of foulness attained by the oil. The top chamber is

* Abstract of paper by Alfred J. Wilson, A.M.I.Mech.E., A.M.I.Pet.Tech., read before the Diesel Engine Users' Association, 21st October 1920.

provided with a floating syphon which when set in operation delivers the settled oil drop by drop into the second compartment, whence it passes by gravity through a special filter pad into the lowest compartment. The descending oil is collected off the underside of the filter pad in the second stage and led into a tube which terminates in a further filter pad. This cleans the oil by upward filtration, the recovered oil falling into the bottom of the third, or lowest, compartment, whence it is drawn off for re-use as required. By heating the oil with steam coils or electric heaters the capacity of the filter can be practically doubled.

Boiling Water Method.

Compound oils can be cleaned by passing them over boiling water.

One of the most satisfactory examples of this system is that installed at the Generating Station of the Chelsea Electricity Supply Company. The waste oil from the engines, excluding that drained from the compressors, is collected into a common tank, whence it is pumped into a larger tank placed at a height of about 8 ft. above floor level. A pipe from this elevated tank is led to a cylindrical open-top tank of about 50 gallons capacity which stands on the floor beneath. This latter tank (fig. 2) is the one used for the boiling treatment, and is filled with water to a height of 12 ins. or thereabouts. The water is raised to boiling-point by means of a steam coil immersed therein. The dirty oil is then slowly fed into the tank by gravity and the

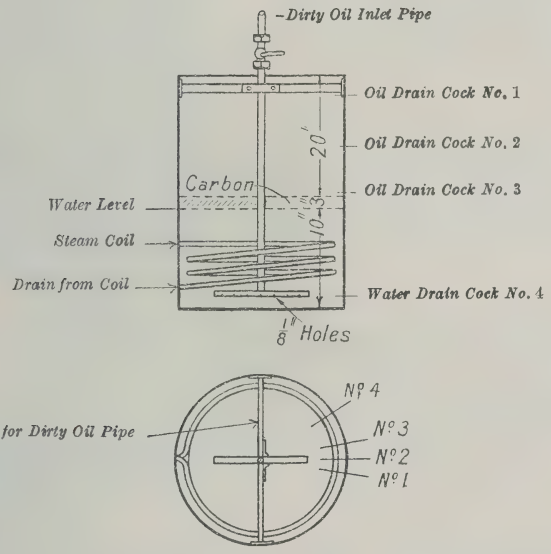

FIG. 2.

flow is regulated by a valve, so that the mixture of oil and water is maintained at a temperature which causes a yellow froth to appear on the surface. When about 30 gallons of dirty oil have been so introduced the supply is shut off and also the steam heater. Settling then takes place and is allowed to continue for some hours, the treated oil being drawn off through cocks at different levels and put into a filter, leaving a deposit of carbon particles on the top of the water. The filter to which the oil is transferred is divided into an upper and a lower compartment, the treated oil when cooled being drawn off by a floating suction pipe and passed into the lower compartment. This arrangement ensures that oil from the upper surface only of the cooled oil shall be passed into the lower compartment, from whence it is drawn off for re-use. No filtering medium is used, the carbon, etc., which has escaped removal in the boiling tank settling out in he first compartment of the filter.

Other methods are those in which :—

(1) The oil is allowed to settle either with or without warming. Objections to this method are the length of time and the large number of settling tanks required.

(2) The oil is warmed and then cleaned by chemical means.

(3) The oil is passed through a centrifugal cleaner.

LUBRICATION.

Crank Chambers.

In engines of the Willans type, in which lubrication is effected by a bath of water with a thin layer of oil on the top, it is generally safer to use a pure hydrocarbon of good body, preferably of the charcoal refined class, which represents the highest lubricative efficiency obtainable in mineral oil. It is important that the oil selected, especially if it is to be used in conjunction with hard water, should be free from tendency to emulsify, as, should this occur in the crank case, lubrication will be much impaired.

For engines lubricated by force, as in the Belliss and some others, an oil of moderate body is required, as, assuming that the bearings are in good condition, the pressure of the pump ought to provide a continual film of oil on each journal. It is also important that this oil should separate freely from water, as the formation of an emulsified magma would interfere with the circulation of the oil.

Crankshaft Bearings.

It is impossible to lay down definite rules in regard to the oil to be used on these bearings, which vary greatly in size, in speed, and in the method of applying the oil. Speaking generally, for large engines lubricated by syphons or by pipes, an oil of good body containing a percentage of fatty oil, ought to be used. It is important to note, in comparing a fatty oil with a mineral oil, that their respective efficiency cannot be determined by body or viscosity alone, as, on account of some hidden virtue in fatty oils, it will be found that a fatty oil of moderate body will reduce friction to a greater extent and will last longer than a mineral oil of much superior body, showing that body by itself as not the final criterion.

Ring Lubrication

introduces another condition apart from the direct question of the immediate efficiency of the oil. In ordinary lubrication the oil is slowly fed to the bearing at a rate calculated to make good the loss by waste or use. The oil, therefore, practically serves only once, but in the case of ring lubrication the oil may remain in use for months with only occasional slight additions to replace waste ; but during all the time that the oil is in use it is being taken up by the rings and spread over the journal and bearing in a thin film continually exposed to the action of the atmosphere. Under these conditions an animal or vegetable oil would, by the absorption of oxygen from the atmosphere, be slowly thickened and become gummy and unsuitable. Therefore, in this case, it is advisable to forgo the advantages offered by fatty oils and to select a pure hydrocarbon oil of suitable body and high boiling point which will not too readily lose bulk by evaporation or be chemically affected by the action of the atmosphere.

Notes on Ring Lubrication.

Sluggish action of the oil-rings of motors in a large New Jersey factory, leading to improper lubrication of the bearings, was cured by bevelling the sides of the rings. On testing the motors it was noticed that the rings would creep along at a very slow speed, two or three revolutions a minute on a machine of several horse-power, instead of the regular speed of about thirty to fifty revolutions. It was finally discovered that under certain conditions a ring would start with the machine and perhaps come up to normal speed, but would soon work itself towards one side of the slot and slow down, hugging closer and closer until there was only a very thin film of oil between the ring and the flat part of the journal. Three rings were removed and their sides were slightly bevelled, when the trouble entirely disappeared.

(*P. G. Bernholz*, '*Electrical World.*')

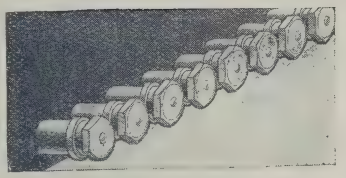
Regular inspection of the oil-rings on generators, converters, or motors should be made by the operator to determine if they are turning properly. This is especially necessary when a machine is started up, as the rings are apt to stick at this time. The fact that the oil need be

TECALEMIT

LUBRICATION SYSTEMS FOR ALL TYPES OF INDUSTRIAL MACHINERY

CENTRAL LUBRICATION

Positive Lubrication under high pressures (150-200 lbs. per sq. in.) may be effected from one central pump. By the single action of a small hand lever, oil is discharged from each main outlet of the pump to as many as 8 to 10 points. A separate discharge chamber and plunger serves each main outlet and the lubricant is controlled at the bearings by special regulator plugs. Pumps are supplied in varying sizes with any number up to five main outlets.



GROUPED NIPPLE SYSTEM

A convenient and simple method of lubricating any number of bearings from one position. The nipples are fitted on a battery plate which is easily accessible with any type of Tecalemit gun.

Lubricant is forced through special smooth bore brass piping to every bearing; there is no risk of any point being overlooked or neglected, and the lubrication of the whole machine is rendered a quick, clean and safe operation.

THE IRONMONGER

HARDWARE AND METAL TRADES ADVERTISER.

ESTABLISHED 1859.

PUBLISHED WEEKLY

28 ESSEX STREET, STRAND, LONDON, W.C.2

For over seventy years The Ironmonger has been the leading newspaper published in the interests of buyers of hardware, metals and mill furnishings.

Its news service is invariably up-to-date and its information reliable, while its weekly record of current prices of staple commodities gives to its pages a world-wide reputation as a valuable buyers' guide for the purchasing departments of engineers, shipbuilders, collieries, etc. etc.

All this information is obtainable for the cost of a year's subscription, £1, which sum includes a copy of The Ironmonger Diary and Hardware Buyers Guide, published each December.

To anyone interested a specimen copy of The Ironmonger will be sent on application accompanied by trade card.

changed only once or twice in a year does not necessarily imply that the bearings are fool-proof and need no attention on the part of the operator. If the rings stick and fail to revolve, the bearing will get no oil. This frequently happens, resulting in an overheated bearing, and sometimes in enforced shutdown of the machine. Consequently, it is an important duty of the operator to make regular inspection of these rings to see that they are turning. If they are not, they should be started with a small hardwood stick, which should be kept on hand for this purpose. At the same time, the operator should see that the gauge glasses on bearings are at least half-full of oil, and that there is no leakage around the glasses. In case of any apparent leakage, lack of oil, or chronic sticking of any particular oil-ring, the matter should be reported to the foreman. When inspecting oil-rings on a running rotary, operators should wear goggles to protect their eyes from possible flashovers.

The rings should be turned and bored truly from extra thick commercial brass tube, and made approximately twice the diameter of the journal it is required to lubricate, and the width about one-half of the shaft diameter. As regards thickness, it has been proved by experiment that the thicker the ring, with its consequently increased weight, the more dependable is the rotation with the shaft, the oil allowing the greater surface of the heavier ring to pass through it with less increase of friction compared with the frictional drive of the heavy ring by the shaft.

Steam Turbines.

The only parts calling for lubrication in turbines are the glands and the external bearings. In the larger sizes both the glands and the bearings are provided with jackets through which water may be circulated, when this is necessary, to keep the bearings cool. In the earlier types of turbines, the glands were packed in the ordinary manner and called for the use of oil of a cylinder character to reduce friction. In modern practice the glands do not call for lubrication, as they are fitted with special metallic ring packing which does not make metallic contact with the shaft. A little water is injected and serves to condense any escaping steam at the high pressure end and the admission of air at the low pressure, or vacuum, end and also in a measure acts as a lubricant.

The lubrication of turbine bearings is usually effected by the circulation of oil by a pump which forces the oil from a tank in the base of the engine through a system of pipes to the bearings, from which it returns by other pipes to the tank through which cold water circulates in pipes to reduce the temperature of the oil.

The conditions calling for consideration in the lubrication of turbines seem to be the abnormally high temperature of the bearings, due to the transmission of heat by the shaft from the turbine, the probability that, despite most careful precautions, water may find its way into the oil, and the fact that the oil may remain in use for many months without change and with comparatively little addition of fresh oil. These conditions call for oil of considerable body, which should not be liable to emulsify in contact with water, and which should not be injuriously affected by long use and contact with air. (See also Section XXX, Part IV.)

Dynamos.

which are generally provided with ring bearings, should be dealt with on the lines indicated in 'Ring Lubrication,' p. 984.

Air Compressors.

See p. 1190.

Shafting

requires oil of moderate body, which may be either a compound oil, if the best results are required or a pure mineral oil if the strain on the bearings is not too great and the system of lubrication ensures a constant and regular supply of oil.

Abrasive Wheels.

See p. 1105.

Automatic Tools.

The high speeds adopted in tools of the turret lathe type, and the great pressure and high temperature developed at the cutting point in large automatic lathes, call for oils of superior quality to save the edge of the tool and the surface of the metal on which it operates; but

although the old-fashioned soap-suds are unsuitable, from their rusting action on the tools and on the metal of the job, it has been found that, in many cases, satisfactory results are, and may be, obtained by the use of a soluble oil, or soluble paste dissolved in water, which keeps the cutters cool and in good condition, and does not rust the job.

Lubrication at High Pressures.

Two examples of equipment operating under heavy bearing pressures are the boring mill and the metal press. Each is a distinct problem, since in the first the pressures are steady, while in the second they are intermittent. The first condition is more complex because of the bearing temperature. However, the pressures existing on the down-stroke of a metal press may be from 4,000 to 5,000 lbs. per sq. in. for a brief period.

For average conditions—*i.e.*, with pressure below 400 lbs. per sq. in.—a highly refined non-emulsifying straight mineral oil having a viscosity of from 180 to 200 secs. Saybolt at 100° F. will normally meet operating requirements. In certain operations, however, thrust pressures in excess of 1,000 lbs. per sq. in. may occur. Such a condition requires a straight mineral steam-cylinder oil of a viscosity of from 130 to 160 secs. Saybolt at 210° F.

See also p. 994.

Lubrication Oil Grooves.

The function of grooves is primarily to distribute oil from the source of supply over the complete length of the bearing. Wherever possible, they must be confined to the unloaded portion of the bearing; the loaded part should be left free from interruptions. It appears that an angle of about 45° to 60° must be had between the line of oil admission and the load line to allow of building up an efficient load-carrying oil-film.

An oil-groove should be well chamfered at its edges, so as to help the oil-film to develop rather than to scrape the film from the journal.

Graphite Lubrication.

Graphite, plumbago, and blacklead are mineralogically similar, but whereas blacklead often consists of a large proportion of clay and very little pure blacklead, on the other hand graphite (especially those grades prepared for very special lubricative purposes) may consist of as much as, and even more than, 99 per cent. of pure graphitic carbon.

The selection and preparation of graphite for lubrication requires the observance of two principal considerations, viz., the structure of the graphite itself and the character and amount of other matter incorporated with it. For instance, a flake graphite, comprising 95 per cent. of pure graphitic carbon having the necessary unctuousness, but mixed with 5 per cent. of hard siliceous rock or quartz, would not be satisfactory for any form of lubrication. Unfortunately, many purchases of such delcterious admixtures are made because the price is lower than, for example, a flake graphite, consisting also of 95 per cent. unctuous graphite with 5 per cent. smooth foliated micaceous matter. The latter, for many purposes, is every bit as good as a 99·8 per cent. or 99·9 per cent. pure flake graphite, and is comparatively much cheaper than grades of such high purity, but its cash value is many times that of the one containing rock or quartz (though the difference in actual cost between the 'quartz' grade and the 'soft mica' grade may only be a few pence per lb.). The damage which such an abrasive mixture will undoubtedly do to any kind of machinery is serious. Engineers should therefore exercise very particular supervision over these purchases.

As already stated, the important points are :—

(1) The structure of the graphite, and (2) the character and amount of the impurities in it.

Flake graphite is necessarily the best for lubrication, when consideration is given to the manner in which its lubricative duties are performed. It is required to associate itself and become attached to, and form part of, one or both of the rubbing surfaces, and impart an even and smooth finish to these surfaces, by filling up any tiny depressions. The way confetti clings to the floor is a good illustration in this connection of the advantage of a flat or flake structure.

In the well-known 'Foliac' brand of flake graphite (of *Graphite Products, Ltd.*), the flake structure is combined with foliations which act similarly to a pack of cards under pressure, by slithering apart and presenting a much larger smooth and slippery surface. This foliated or laminated structure is a distinct feature of these products, and it is claimed that a much lower coefficient of friction is obtained with them than with, e.g., the amorphous varieties of graphite or plumbago, whether carried to the surface in colloidal form or not. In connection with colloidal or deflocculated graphites it must be remembered that acidity, alkalinity, or other disturbing cause is necessary in order that the colloid may flocculate into particles large enough to attach themselves to bearing surfaces.

Recent examinations of representative samples of 'Foliac' flake graphites showed the following results :—

Foliac No. 1,	assayed,	96·00	per cent.	carbon.
Foliac No. 2,	,,	95·50	,,	,,
Foliac No. B1371,	,,	96·13	,,	,,
Foliac No. 100,	,,	99·85	,,	,,
Foliac No. 101,	,,	99·75	,,	,,

Because graphite has a higher specific gravity than oils (about 2·2 to, say, 0·9 or so for oil) it is impossible to permanently suspend it in ordinary lubricating oils, at any rate without special and complicated treatment; therefore, in order to convey flake lubricating graphites to bearing surfaces with certainty and regularity, suitable greases with the graphite in intimate admixture are best. Many instances are recorded where suitable flake graphite greases have outlasted other kinds (without flake graphite) five or six times and with less friction.

The Use of Graphite.

The right kind should be selected for a specific purpose. As examples, the large flake is best suited to large areas of surface, whether bearings, cylinders or valve faces; and the small flake is best for smaller areas of surface. At the same time, for intricate, fine or fast moving motions, it is well to select a specially prepared fine flake graphite for these purposes.

All surfaces in frictional contact should be well rubbed with the selected flake graphite for any particular class of machinery, before assembly. This rubbing is best done by dipping a clean oily pad in the graphite, and rubbing it well into the surfaces. The smoothness and consequent reduction of friction is most noticeable, and it is a very long time before this 'graphite skin' or polish is lost.

The removal of the flake graphite after this rubbing in can only be done by filing or grinding—in other words, to remove it, the surface or the metal itself has to be removed.

For regular use after assembly of parts, as already stated, one of the flake graphite greases is best, but occasional doses of flake graphite can be fed with the ordinary lubricating oil with most satisfactory results. It will be obvious that the large flake graphite mixed with a thin spindle oil will settle much faster than a very fine flake graphite in a bodied engine or heavy machine oil.

Too much should never be used, especially when mixed with oils—from 2 per cent. to 5 per cent, according to the service required, is usually ample. With greases, the proportion may be larger.

Graphite, particularly the flake variety (if free from abrasive matter), is an exceedingly useful and beneficial product—but it should not be used to excess, as too much is likely to give trouble.

Feeding Graphite.

In the first place, when erecting or repairing engines, or whenever the cylinders and valves are opened, the working surfaces should be freely covered with a thick mixture of graphite and cylinder oil. Flake graphite cannot satisfactorily be fed through the usual sight-feed displacement lubricators for the reason that its high specific gravity causes it to settle in the oil and to clog up the connecting pipe. A reasonable doubt might be entertained as to whether graphite can readily become attached to the frictional surface if it is so fine that it passes through the pores of filter paper, as is claimed by some, which would indicate that the particles of graphite are surrounded by an unbreakable oil film. But if these particles could become attached to the frictional surface, efficient but not lasting aid to lubrication would certainly result. Experience seems to show that there is a limit to a desirable subdivision of graphite, and if this is so the settling of graphite in cylinder lubricators must be overcome by mechanical means, since even the smallest particles of graphite which can be seen will settle in oil. There are, however, cylinder lubricators on the market for feeding graphite, the best known of which relies on continuous stirring to secure suspension of the graphite, even in the delivery pipe, by means of a spiral wire which is constantly turning.

Graphite as a Lubricant for Cylinders.

As a cylinder lubricant, flake graphite has come to be widely used, as it is quite unaffected, either chemically or physically, by any temperature encountered in a cylinder and retains its high lubricating value even when at a red heat.

Wells and Scott-Taggart, in their book 'Cylinder Oil and Cylinder Lubrication,' write concerning the oil polish as follows: 'In order to satisfy themselves as to the working of an oil, most engineers open the cylinders at intervals and note the condition of the surfaces. Satisfaction is generally felt if they find the inside of the cylinder polished like silver, or if it has a bright, smooth surface, "like a mirror," as some express it. Now, this is not by any means the condition the cylinder ought to be in, if it is lubricated with oil alone. Suppose an engineer found, on opening the cylinders of his engine, that bright streaks existed, he would conclude at once that the bright spots were the result of friction . . . Strange to say, if he found the whole surface of his cylinder polished, he would not think it was friction. A well-lubricated cylinder ought to present a rather dark-looking surface, smooth, but with no signs of bright polish, even if coated with oil. The slightest rubbing with a polishing rag would produce a bright surface on such a cylinder, thereby proving that the lack of a polish is due to the absence of friction.'

In addition to the 'oil polish' referred to above, there is the smoothing and polishing effect produced in ammonia cylinders of refrigerating machinery, the 'water polish' frequently observed in marine engines and in pump cylinders, and the 'graphite polish.' This last is different from the others, which are really friction polishes, obtained by rubbing off the roughness of the grain of the metal. Graphite polishes by filling in the grain of the metal, just as wood filler and varnish polish a surface of wood, and cannot therefore be construed as an evidence of friction.

The question of the best manner of separating graphite from exhaust steam is frequently raised by those not familiar with its use. In answer it may be said that any separator, grease extractor, or settling tank that will remove even a fair percentage of cylinder oil will remove all the graphite that goes out with the exhaust. Graphite passing into a separator is apt to adhere to the baffle plates, and it is good practice to remove and clean them from time to time.

Where measures are not taken to separate or otherwise eliminate such graphite as may leave the cylinder with the exhaust steam, certain small amounts may pass into the boiler with the feed water. Graphite in a boiler is an advantage rather than a detriment. If the feed water contains scale-forming salts, the graphite will combine with the scale to make it softer and more easily crumbled. The heat transfer will not be affected, for graphite is a very good conductor of heat. (See also 'Foliac Boiler Graphite,' p. 1627.)

Graphite as a Lubricant for Gas Engines.

An authority on gas-engine cylinder lubrication has stated that the perfect lubricant for this work should either be consumed entirely or else not at all. Flake graphite meets this last requirement fully, since the intense heat encountered in a gas-engine cylinder has no effect whatever on graphite. There are many ways of feeding graphite for gas-engine cylinders, as there are many types of gas engines, but space does not admit of a full description of the different methods. Inhalation of dry graphite from a closed container or cup attached to the inlet pipe into the gas and air mixing chamber has been successful, the pulsations due to alternate compression and reduction of pressure allowing a little graphite to feed through the hole (say $\frac{3}{32}$ in. diameter) in the bottom of the container.

Difficulty has sometimes been encountered with graphite by its short-circuiting sparking points in jump-spark ignition. This usually means that too much graphite has been used, and reducing the quantity removes the trouble.

Lubrication Troubles from Uncleaned Castings.

When a new engine or turbine is first set to work, there is certain to be trouble with bearings in perhaps a majority of cases. This is because so many constructors neglect the proper cleansing of castings. Castings are never properly cleaned of sand even externally by the still common methods of steel brushing and coke rubbing, and in steam ports and passages it is hopeless to expect cleanliness from such antiquated methods. 'Sandblasting' with chilled-steel pellets will clean a casting externally, but cannot be relied on for the internal cleansing of ports or oil receptacles. Thus it is that lubrication troubles are so usual when starting up new sets. Some engineers strongly favour the pickling of castings as the most effective way of removing sand. The castings are first roughly cleansed and fettled, and then hosed with weak hydrochloric acid. Where sand is present this spreads the acid by capillary action, and the result of a few hours of acid action is to remove all sand and leave the iron surfaces clean and free also from the hard siliceous scale which is so destructive of turning tools and other tools, especially millers, and is also most injurious to lathe-bed surfaces and other working surfaces of all machine tools. When the acid treatment has done its work, the castings are washed by warm water, and this may be dosed with soda to neutralise any unspent acid.

Note on Lubrication.

Special attention should be given to all internal parts such as box beds, which act as oil receptacles, as well as to steam and exhaust passages. The oil of any circulating system becomes dirty with use. Dirt comes over from the boilers with the steam and finds its way into turbine bearings in spite of all the constructive care to guard against this. The atmospheric dust gets in somewhere, and there may be leakage at oil coolers. There is also the microscopic metallic waste from bearings. All these sources of dirt are quite enough to call for filtration, apart from the gross carelessness which is shown by the presence of foundry sand. Oil may sometimes be at fault if it has been chosen wrongly, but more usually sand, which ought never to have found itself so far from the foundry, is to blame. Organic oils deteriorate with age owing to their property of absorbing oxygen: this causes them to become gummy or resinous, and thus to lose their lubricating quality. Mineral oils, which are not, chemically speaking, oils, do not absorb oxygen, and are free from this deterioration.

LUBRICATORS.

The V.S.M. Automatic Forced Lubrication System.

In the V.S.M. System of Lubrication (*Messrs. Vickers, Ltd.*) the oil is forced in between the shaft and its bearings at the point of maximum pressure. This is done by means of a pump, which is only about $\frac{3}{8}$-in. diameter, with a stroke of about $\frac{5}{16}$ of an inch. Preferably one such pump is provided for each bearing. The pump works in a closed circuit of oil, and the same oil used over and over again. *Whenever the pressure per square inch between the shaft and its bearing increases, due to the weight of the shaft or to external stresses, the pump automatically raises the pressure of oil to meet and overcome this resistance, and forces it through to form a positive and unfailing film between the two surfaces exposed to maximum pressure.*

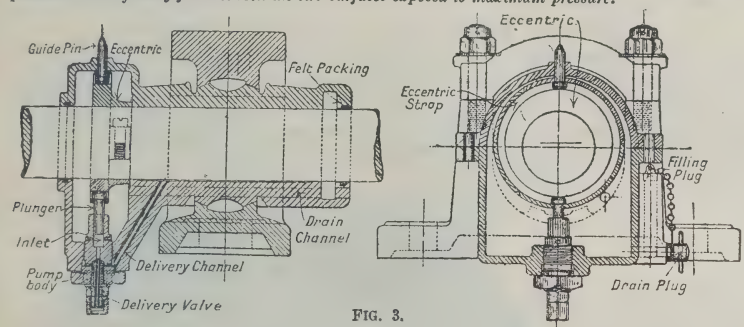

FIG. 3.

Fig. 3 shows the forced lubrication system applied to a $2\frac{1}{2}$-in. swivel bearing. The pump is surrounded by a reservoir of oil, which has the effect of flooding the inlet openings in the pump body. In this way a suction valve is dispensed with, and the pump plunger is, in effect, its own valve.

The action of the pump is as follows: When the plunger rises to the top of its stroke the inlet openings in the pump body are fully exposed, and oil from the reservoir flows in through these openings, filling the available space in the pump chamber. In making the return stroke the pump plunger gradually passes the inlet openings and finally cuts off the connection between the pump chamber and the external reservoir. The remainder of the downward stroke forces the oil imprisoned in the pump chamber past the non-return delivery valve into the delivery channel, and thence into the bearing on the surface exposed to maximum pressure. This action is repeated with every revolution of the shaft, and in large slow-running shafts the eccentric can be replaced by a cam giving two or more pump strokes per revolution as required.

Each stroke of the pump delivers a definite volume of oil to the bearing, and at the same time displaces an equal volume from the bearing. The displaced oil falls into the chambers provided at each end of the bearing, and flows back, by simple gravity only, into the reservoir surrounding the pump.

In cases where the V.S.M. System of Lubrication has to be applied to bearings and structures already in existence, and where it is impossible to incorporate the V.S.M. apparatus in the design and structure of each bearing, a multiple pump arrangement is adopted consisting of a number of units up to twelve in number. The principle of the arrangement is exactly the same as that shown in fig. 3. To ensure that each bearing gets its proper supply of oil, a separate pump is provided for it, with delivery pipe.

The multiple pump can be driven by a belt or chain, or it can be coupled up to another shaft. The eccentrics operate the pumps exactly as described. The oil flows by gravity from the reservoir past the stop valve through channels to the regulating valves. The oil drops by gravity into the suction side of the pump, and is then forced past the delivery valve on the way to the bearing to be lubricated. Glass tubes are provided for convenience to exclude dust and yet at the same time to enable one to watch the amount of oil passing to each bearing.

In the application of the V.S.M. system to an axle-box for railway rolling-stock the eccentric pump and accessories are substantially the same as those used for ordinary fixed bearings. With fixed bearings, however, the pressure on the bearing itself is usually on the under side, but in railway axle-bearings the pressure is on the top side, and in addition the bearing on the under side is entirely cut away. In consequence it is necessary to provide a short pipe, preferably of copper, to convey the oil from the pressure side of the pump to the top of the bearing at the point of maximum pressure. This arrangement permits the oil pump to be fixed at or near the bottom of the oil reservoir, ensuring an ample supply on the inlet side of the pump. The copper pipe leading from the pressure side of the pump to the top of the bearing is made long with bends, so that any relative movement between the top bearing and the pump may take place in the bends without stressing the unions at both ends of the pipe. Preferably the pump itself is designed as a separate piece from the axle-box for the purpose of manufacture, inspection, and more convenient application to the axle-box.

With a railway axle-bearing having an oil reservoir the great difficulty is to prevent the surplus oil escaping along the axle through the inner end of the axle-box, and so rapidly emptying the reservoir. Another difficulty is to prevent the dust entering through the same space and acting as an abrasive on the axle and its bearings, and causing the rapid wear of both. To overcome these difficulties a special ring has been provided to act as a dust excluder and oil retainer.

The Hulburd Valveless Force-Feed Mechanical Lubricator.

(Hulburd Patents Ltd., 26, Park Road North, Acton, London, W. 3.)

The Hulburd Valveless Force-Feed Mechanical Lubricator (for locomotive cylinders, steam chests, axle-boxes, etc.), fig. 4, is a thoroughly reliable instrument of robust construction and extreme simplicity ; it thus affords adequate guarantees as to durability and low-working costs. It is entirely without valves, either suction or delivery, and, being positive in action, it makes air locks impossible, and will start to work automatically without the preliminary hand manipulation necessary in the case of previously existing types.

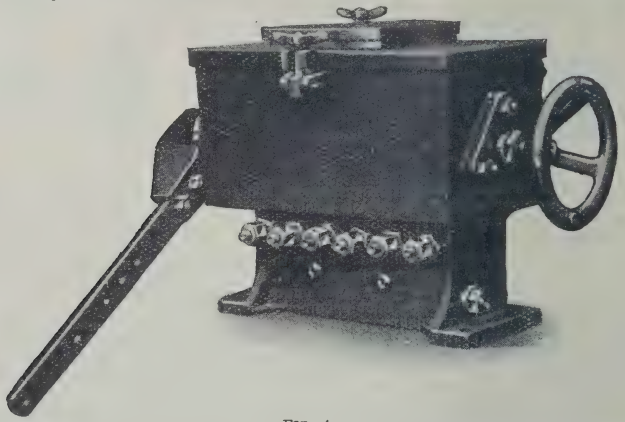

Fig. 4.

The working parts of the valveless lubricator have been reduced to the lowest possible number. As they are all self-lubricating and, being enclosed, efficiently protected from grit or dirt, long life is assured and wear reduced to a minimum.

The design of the valveless lubricator permits the use of the thickest oil or a mixture of oil and graphite or even grease, the absence of valves and restricted passages enabling it to deal with lubricants of practically any consistency ; thus the usual provisions for warming the container, being unnecessary, are entirely dispensed with.

The principle of action of the valveless lubricator is that of two opposed plungers working in a common cylinder. Of these plungers one has a continuous reciprocating motion imparted to it, and the other, normally carried with the first and partaking of its movement, is arrested and held stationary at suitable intervals so that they mutually separate from and approach each other, thereby in turn closing the inlet and outlet ports and producing the suction and discharge strokes which are thus rendered effective without valves of any description.

There being no delicate springs or valves to be put out of action by every small obstruction, and no narrow and intricate passages to become blocked, the lubricator is rendered unchokeable, and all working parts, being within the oil container, are not only effectively protected from dust and dirt, but are also continuously lubricated without extraneous attention, so that neglect under that head has not to be reckoned with, the whole being entirely automatic.

The valveless lubricator is positive in its action, and ensures a uniform rate of feed against all pressures and under all conditions; it delivers, as regulated, a definite charge of lubricant at every stroke which is forced in its entirety to the desired point.

One of these lubricators, after running the equivalent of some 40,000 miles at the rate of 60 miles per hour, and forcing oil against an average pressure of 175 lbs. per sq. in., was dismantled, and it was impossible to detect any wear on any of the working parts; the pump plungers after being measured on a micrometer were found to be exactly as they were before the test started; also during the test the amount of oil delivered was carefully measured at intervals and found to be absolutely constant throughout.

The 'Tecalemit' High-Pressure Lubrication System.

(*Tecalemit Ltd.*, 10 *Little Portland Street, London, W.* 1.)

This system consists of lubricating plugs (fig. 5) fitted with a non-return valve, which takes the place of the Stauffer type or drop-feed lubricator. These plugs can be supplied with any required male or female thread, or can be supplied for fitting to plain bored holes.

Fig. 5.—Hook-on plugs.

A 'Gun,' which is operated by hand, is used to supply the lubricant to these plugs. This consists of a lubricant receptacle (fig. 6) of $2\frac{1}{2}$, 5, 10, or 17 ozs. capacity, fitted with a handle which forces the lubricant into a small high-pressure cylinder. When the gun is applied to the plug or lubricating point, either by sliding it on in the case of the 'Automatic' type, or by simply pressing it on in the case of the 'Tecalemit Z' type, a leak-proof connection between the gun and the plug is automatically made, and, by applying further pressure, the high-pressure cylinder telescopes into a small piston fitted inside the nosepiece, and forces the lubricant under a pressure of 5,000 lbs. to the square inch through the plug and on to the bearing.

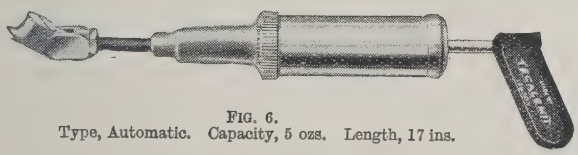

Fig. 6.
Type, Automatic. Capacity, 5 ozs. Length, 17 ins.

If there are sufficient lubricating points to justify the outlay, there is the Tecalemit transportable workshop pump, capacity 17 lbs. of lubricant, on four small wheels, or the 11 lbs. capacity knapsack pump, arranged to be strapped on the operator's back. The former type is only suitable for the Tecalemit slide-on nozzle, whilst the latter can be used with either the slide-on or the push-on nozzles. The pressure obtainable is 5,000 lbs. per square inch.

A special pattern of portable lubricating tank, capacity 100 lbs., is made, which is suitable for any type connection. With this tank a high output of lubricant under low pressure can be

obtained, or, by screwing on one of the nosepieces delivered with the apparatus, a large number of points can be lubricated under 5,000 lbs. pressure with two turns of the handle. This machine is in considerable demand for large workshops, tramway depots, etc.

Notes on Lubrication and Lubricators.

Much money is wasted and poor operating results are obtained through paying good money for good lubricants and applying them in a haphazard manner by means of unsuitable devices. A good lubricating device is almost as important as a good lubricant, and different conditions require different types of oil or grease cups. These conditions should be investigated and a proper device adopted.

In general, leaky connections on a lubricator will cause irregular feeding of the oil. Should the sight-feed glass become clogged, it may be due to setting up too tightly on the bottom nut when the glass was installed. This often causes the rubber gasket to be squeezed out of place and perhaps into the glass. If the oil-feed cone should become displaced or off centre, it may cause the globules of oil to move up the sides of the glass, and perhaps to stick there, causing the glass to fill with oil. The glass should then be removed and the cone filed down, or it will be found effective to solder a fine copper wire to the side of the cone, leading it upward through the centre of the glass, nearly to the top. The oil drop will then follow the wire, and the glass will remain clean. It is not advisable to allow a hydrostatic lubricator to run empty of oil, owing to the danger of the sight-feed and gauge glasses becoming hot, thus causing oil to stick to the sides of the glass.

SECTION XX

PART III

VISCOSITY AND VISCOUS FLOW OF OILS.

VISCOSITY OF OILS.

Oils of a particular description may vary largely in kind; 'shale' oil, for example, may vary from petrol to heavy oil, and other descriptions may also vary; the names of the oils referred to in the following table cannot therefore be taken as being characteristic of their viscosity.

TABLE I.—VISCOSITY TESTS OF VARIOUS OILS.

(Referred to in Tables II, III, and IV.)

No.	Description.	Origin.	Colour	Density (δ) at 20° C.	Redwood Viscosity Number at 20° C.
1	Shale	—	Dark brown	0·8530	8·25
2	Fuel	Burma	Dark brown	0·8890	14·8
3	Refined machine	—	Pale yellow	0·8630	21·8
4	Olive	—	Yellow	0·9130	69·3
5	Refined spindle	Russia	Pale brown	0·8955	76·3
6	Fuel	Texas	Black	0·9310	126·0
7	Engine	Russia	Brown	0·9055	255·0
8	Fuel	Roumania	Black	0·9495	579·0

TABLE II.—CHANGE OF VISCOSITY BY CHANGE OF TEMPERATURE.

No.	Percentage rate of change of viscosity per 1° C.*									
	20°	25°	30°	35°	40°	45°	50°	55°	60°	65°
1	3·2	3·0	2·8	2·6	2·5	2·4	2·4	2·4	2·5	2·6
2	4·7	4·1	3·8	3·5	3·1	2·9	2·7	2·6	2·5	2·6
3	—	4·5	3·8	3·4	3·2	3·3	3·4	3·6	3·9	4·4
4	4·7	4·4	4·2	4·0	3·7	3·4	3·2	3·2	3·5	4·1
5	7·0	5·7	5·3	5·5	5·7	—	—	—	—	—
6	—	—	6·1	5·1	4·8	4·6	4·4	4·4	4·4	4·4
7	—	—	5·6	5·4	5·9	—	—	—	—	—
8	—	—	6·5	6·1	6·2	6·7	—	—	—	—

* The values given in the table must be divided by 1·8 to obtain the percentage rate of increase of viscosity per 1° F.

TABLE III.—DENSITY (δ).

No.	Temperature ° C.

CHANGE OF VISCOSITY BY CHANGE OF PRESSURE.

Experiments made by the National Physical Laboratory have shown that at a pressure of 9,000 atmospheres, the viscosity of animal oils was about 4 times as much as at atmospheric pressure, but in the case of mineral oils the increase was as much as 16-fold.

VISCOUS AND TURBULENT FLOW.

(1)

Although there are two kinds of flow, viz. 'stream line' or 'viscous' flow, and 'turbulent' flow, for all practical conditions, heavy oils, Mexican oils, and others, follow the law governing viscous flow.

The frictional loss due to purely viscous flow is given by the equation

$$H = 0{\cdot}0066875\ \frac{TVP}{d^2}$$

where,

H = loss of head per 100 ft. of piping;
T = viscosity measured in secs. by Redwood No. 2 Viscometer;
V = velocity in ft. per sec.;
P = weight in lbs. per cub. ft.
d = diameter of pipe in ins.
(*G. & J. Weir, Ltd., Cathcart, Glasgow.*)

If

Red. = Redwood viscosity number;
W = weight in tons per hour of oil passing through pipe;
δ = oil density;

then,

$$T = 4{\cdot}895\ \frac{\text{Red.}}{\delta};\quad V = 1{\cdot}83\ \frac{W}{d^2\,\delta}\ \text{ft. per sec.};$$

* See p. 978. The 'viscosity' of a substance is measured by the tangential force on unit area of either of two horizontal planes at unit distance apart, one of the planes moving with unit velocity relatively to the other.

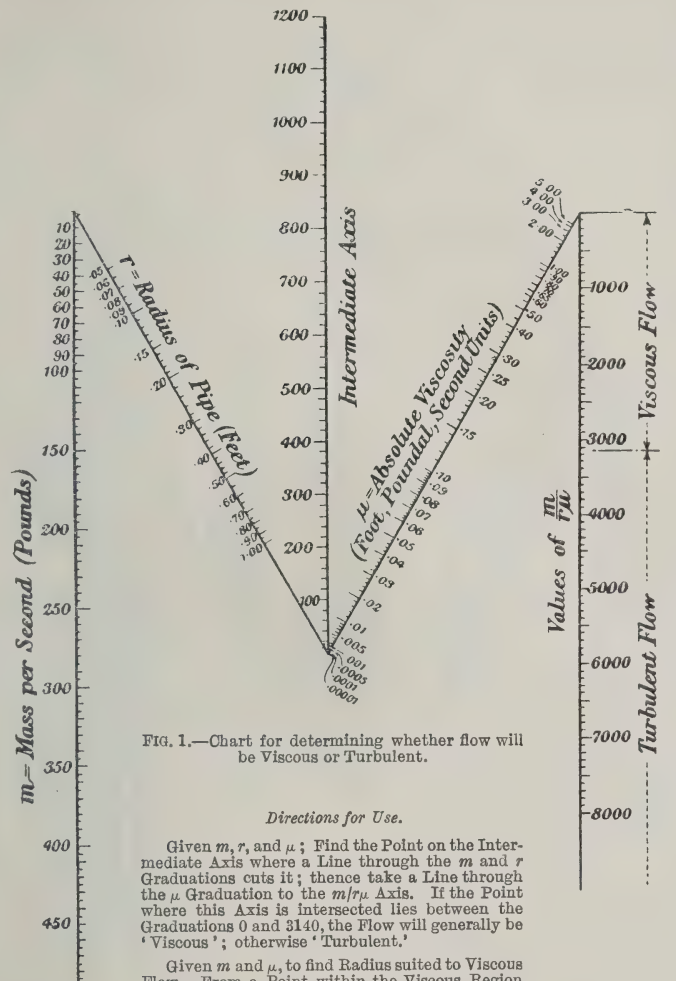

FIG. 1.—Chart for determining whether flow will be Viscous or Turbulent.

Directions for Use.

Given m, r, and μ; Find the Point on the Intermediate Axis where a Line through the m and r Graduations cuts it; thence take a Line through the μ Graduation to the $m/r\mu$ Axis. If the Point where this Axis is intersected lies between the Graduations 0 and 3140, the Flow will generally be 'Viscous'; otherwise 'Turbulent.'

Given m and μ, to find Radius suited to Viscous Flow. From a Point within the Viscous Region on the $m/r\mu$ Axis take a Line through the μ Graduation to the Intermediate Axis. A Line thence to the m Graduation will give the Radius for a Pipe in which the Flow will be 'Viscous.'

('*Engineering.*')

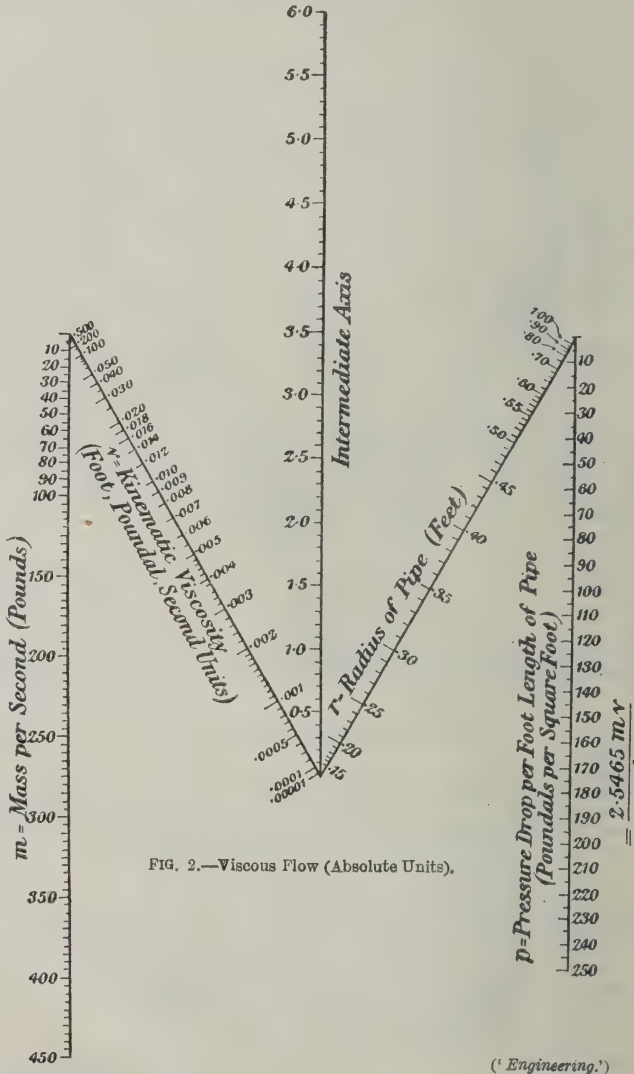

FIG. 2.—Viscous Flow (Absolute Units).

('*Engineering*.')

TURBULENT FLOW.
(ABSOLUTE UNITS.)

First Term in Lees' Equation,

$$p = \frac{\mu^{0.35}\, m^{1.65}}{55{\cdot}08\, r^{4.65}\, \rho} + \frac{{\cdot}0001824\, m^2}{r^5\, \rho}$$

= Pressure Drop in Poundals per Sq. Ft., per Lineal Ft. of Pipe = $p_1 + p_2$, say.

Add the Reading, p_1, on the Right-Hand Axis of this Chart, to the Reading, p_2, on the Right-Hand Axis of the Chart for the Second Term in the above Equation. The Sum is the Total Pressure Drop.

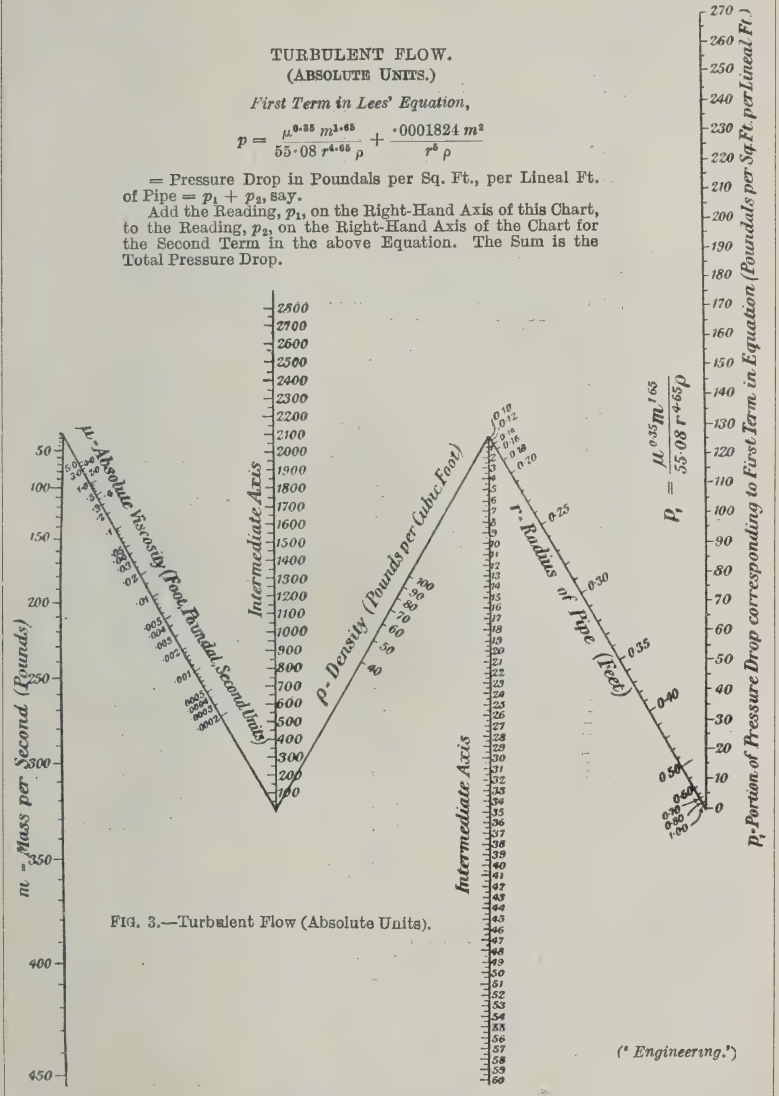

FIG. 3.—Turbulent Flow (Absolute Units).

('Engineering.')

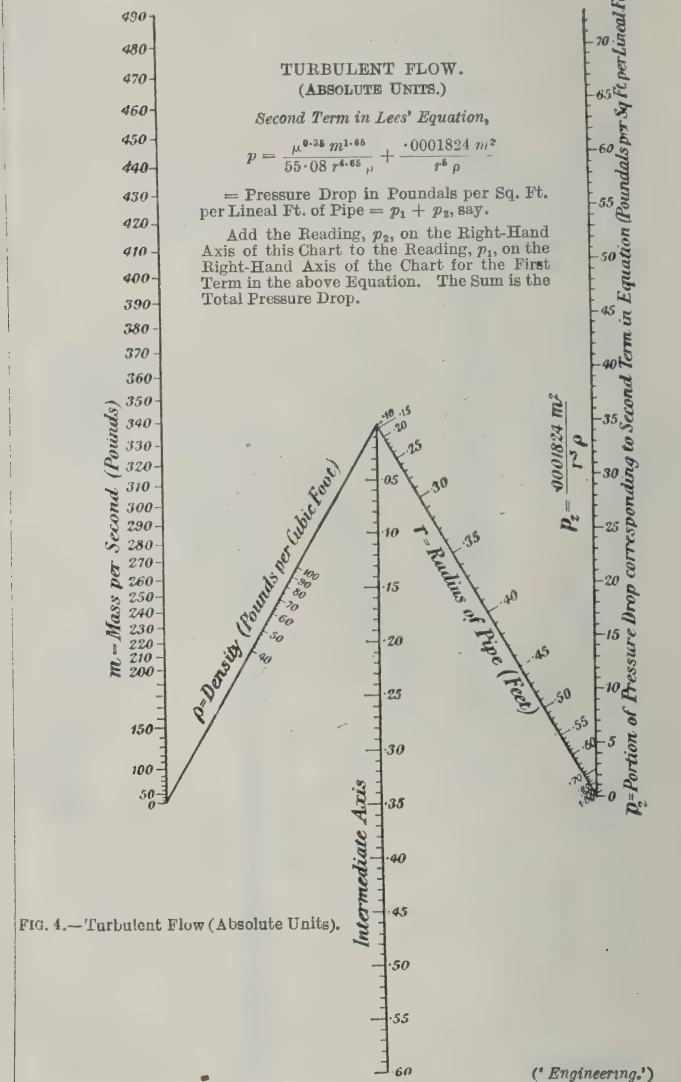

FIG. 4.—Turbulent Flow (Absolute Units).

('Engineering.')

$$H = 2{\cdot}09\ \frac{\text{Red. V.}}{d^2} = 3{\cdot}73\ \frac{\text{Red. W.}}{d^2\,\delta} \qquad (H.\ R.\ K.)$$

Example.—124 tons (W) per hour of No. 8 oil, Table I. p. 993, is to be pumped through a straight length of 9-in. diameter (d) pipe, 50 ft. long. What is the frictional loss (H) ?

From Table I., Red. = 579, $\delta = 0{\cdot}9495$, therefore,

$$H = 3{\cdot}73\ \frac{579 \times 124}{9^2 \times 0{\cdot}9495} = 3{\cdot}73\ \frac{579 \times 124}{6561 \times 0{\cdot}9495} = 43 \text{ ft.};$$

or,

$$43 \times \frac{50}{100} = 21{\cdot}5 \text{ ft. for 50 ft.}$$

See also 'The Design of Oil Fuel Pipe Lines,' by W. G. Watkins, *Engineering*, *Dec.* 19 *and* 26, 1924.

(2)

Oils of various degrees of viscosity are frequently pumped through pipes from the oilfields to ships or to distant storage tanks. To determine the power required in a given case, and to choose the most economical installation of pumping plants and pipes, bearing in mind the life of the field, it is necessary to know the frictional resistance encountered by the liquids when so transported. Such resistance will follow one or other of two laws, according to the viscosity and velocity of the liquid, and it is desirable to have at hand ready means of determining which law to apply in a given case. Having determined this, one proceeds to ascertain the magnitude of the resistance. If the flow is viscous, or, as it is sometimes called, stream-line, all the particles then moving parallel to the axis of the pipe, the resistance can be calculated in terms of the viscosity, density, and velocity. If, however, the flow is turbulent, frictional resistance cannot be found from first principles, and resort must be had to experiment, as in the case of the flow of water. Extensive experiments have been carried out with the object of discovering a law connecting viscosity, density, and velocity when the flow is of a turbulent character, and, in this connection, the work done at the National Physical Laboratory, Teddington, takes a foremost place. Various formulæ have been deduced from these experiments, and, of these, probably none is so reliable as that of Professor C. H. Lees; the charts, figs. 1, 2, 3, and 4, are based on his formula.

As the handling of the formulæ for both stream-line and turbulent flow is somewhat difficult in practice, especially when trials must be made of several different schemes, attention has been directed to the use of graphic methods for displaying the results. The alignment charts shown were prepared for the purpose by Mr. George Higgins, formerly lecturer in Civil Engineering at the University of Melbourne.

The chart shown in fig. 1 may be used for determining which of the two laws will be followed when the quantity flowing, its viscosity, and the size of the pipe are known. Directions for the use of this chart are given at its foot, and other uses to which it can be applied are also indicated. For liquids of high initial viscosity, the practice on the oilfields is to apply heat at intervals along the pipe line, and thus reduce the resistance to flow by reducing the viscosity. When this is done, the average viscosity between heating stations is estimated, and the resistance calculated for this average.

The chart fig. 2 is to be used when the chart fig. 1 indicates that the flow will be 'viscous,' *i.e.* stream-line. Given the quantity and kinematic viscosity, *i.e.* the ratio of the absolute viscosity to the density, then a straight line drawn through the axes for mass and kinematic viscosity at the appropriate graduations, will cut the intermediate axis in a certain point. From this point, a straight line drawn through the appropriate point on the radius axis will cut the right-hand axis at a graduation corresponding to the loss of pressure per unit length. It will be seen that swinging the latter line up or down about the said point on the intermediate axis as centre, will show how the adoption of one radius or another will affect the loss of pressure, and the most suitable radius can thus be more quickly found than by repeated calculations using the formula.

Charts figs. 3 and 4 are to be used when the chart fig. 1 indicates that the flow will be 'turbulent.' Here the complexity of the formula rendered it necessary to separate the factors of viscosity and density, and also to construct two charts, the results of which are to be added together. The method of using these two charts is quite similar to that explained when describing the chart fig. 2, except that the chart fig. 3 involves the drawing of three lines across the graduated axes instead of two. Their employment dispenses with much troublesome tentative calculation when the object is to determine the most suitable combination of pumps and pipes in a given case.

In practice, the lines are not, as a rule, actually drawn across the axes, a straight edge or thread being employed; a very suitable appliance for the purpose is a transparent set-square.

PUMPS FOR VISCOUS LIQUIDS.

See Section XXV, Part II.

SECTION XX

PART IV

SHAFTING AND SHAFTS.

Horse-power of Shafting.

WROUGHT-IRON SHAFTING.

Wrought-iron shafting is now but seldom used. The diameter required to transmit any orse-power may be calculated from the formula :—

$$\text{Diameter of a wrought-iron shaft, in inches, at bearings} = 5\sqrt[3]{\frac{\text{Horse-power}}{\text{Number of revolutions per minute}}}$$

STEEL SHAFTING.

If D = shafting diameter ; R = revs. per min. ; H.P. = horse-power transmitted, hen,

$$\text{H.P.} = D^3 \times R \times 0{\cdot}02.$$

POWER THAT STEEL SHAFTING WILL TRANSMIT AT VARIOUS SPEEDS.

NOTE.

The faster a shaft revolves under the same horse-power, the less is the torsional strain upon it.

Hollow Shafts.

Hollow shafts resist torsion better than solid ones of the same area of metal.

If D = outer diameter;

d = inner diameter,

then,

$$\text{Breaking torsion force, in lbs.} = \frac{(D^4 - d^4) \times \text{Constant}}{\text{Leverage in feet} \times D^3}$$

Distance between Supports in Ordinary Shafts.

If d^2 = diameter of shaft, in inches;

l = distance between supports, in feet,

then,

$$l = 5\sqrt[3]{d^2},$$

where no power is taken off between the supports.

FRANCIS'S TABLE, WHERE POWER IS TAKEN OFF BETWEEN SUPPORTS.

Diameter of Shaft, in Inches.	Distance between Bearings, in Feet.	
	Wrought-iron Shafts.	Steel Shafts.
2	15·46	15·89
3	17·70	18·19
4	19·48	20·02
5	20·99	21·57
6	22·30	22·92
7	23·48	24·13
8	24·55	25·23
9	25·53	26·24

Where power is taken off by rigger between supports, each case should be separately considered ; 7 to 12 feet is usual.

Speed of Shafting.

Shafting for metal-cutting machines . . . 200 revolutions per minute.
" for wood-working . . . . . 250 " "
" for cotton and woollen mills . . . 300 " "

Hollow shafting has been run at 600 revolutions per minute.

DIAMETER OF AXLE, CRANK-PIN, AND SHAFT.

Diameter of Axle.

d = diameter in inches, in the bearing ; and the length of the bearing, $1{\cdot}5d$.
W = weight in pounds, acting in the bearing.

Waterwheels.

$d = \frac{\sqrt{W}}{18}$, for cast iron.

$d = \frac{\sqrt{W}}{21}$, for wrought iron.

$d = \frac{\sqrt{W}}{26}$, for steel.

Common Machinery in good order.

$d = \frac{\sqrt{W}}{24}$, for cast iron.

$d = \frac{\sqrt{W}}{28}$, for wrought iron.

$d = \frac{\sqrt{W}}{34}$, for steel.

EXAMPLE.—A waterwheel weighs 58,680 lbs., and is supported in two bearings. Required the diameter of the wheel axles. The weight acting in each bearing will be $\frac{58680}{2} = 29{,}340$ lbs., and diameter $d = \frac{\sqrt{29340}}{21} = 8{\cdot}15$ inches of wrought iron.

Diameter of Crank-pin.

$d = \sqrt{\frac{F}{1200}}$, for wrought iron. $\quad d = \sqrt{\frac{F}{1570}}$, for steel.

Length of pin $= \frac{3d}{2}$.

EXAMPLE.—The pressure on pin = 27,000 lbs. Required the diameter and length of pin of wrought iron.

$$d = \sqrt{\frac{27000}{1200}} = 4\tfrac{3}{4} \text{ inches.}$$

Length of pin $= 4\frac{3}{4} \times \frac{3}{2} = 7$ inches.

Diameter of Shaft.

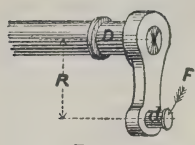

FIG. 1.

D = diameter of shaft, in inches. R = Radius of crank, in feet.
F = force from the steam piston, in pounds.

$$D = \sqrt[3]{\frac{FR}{80}}, \quad F = \frac{D^3 \times 80}{R}, \quad \text{for wrought iron.}$$

$$D = \sqrt[3]{\frac{FR}{120}}, \quad F = \frac{D^3 \times 120}{R}, \quad \text{for steel.}$$

EXAMPLE.—The force on the piston in a steam-engine is F = 45,600 lbs., applied direct on a crank of R = 3 feet radius. Required the diameter of the shaft, the latter being of wrought iron.

$$D = \sqrt[3]{\frac{45600 \times 3}{80}} = 11{\cdot}96 \text{ inches.}$$

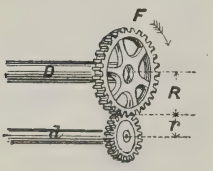

FIG. 2.

$$D = \sqrt[3]{\frac{H}{n} \times 125}, \quad \text{for wrought iron.}$$

$$D = \sqrt[3]{\frac{H}{n} \times 83{\cdot}3}, \quad \text{for steel.}$$

H = the horse-power transmitted. n = the number of revolutions per minute.

$$D : d :: \sqrt[3]{R} : \sqrt[3]{r}, \quad \text{or,} \quad d = D\sqrt[3]{\frac{r}{R}}.$$

EXAMPLE.—A cog-wheel of R = 6·5 feet radius is to gear with a pinion of r = 1·25 feet radius, and to transmit an effect of 231 horses (H) with 42 revolutions per minute (n). Required the diameter of the wheel and pinion shafts. The force F is acting uniformly at the periphery.

Diameter of wheel-shaft $D = \sqrt[3]{\frac{231}{42} \times 125} = 8{\cdot}8$ inches.

Diameter of pinion-shaft $d = 8{\cdot}8\sqrt[3]{\frac{1{\cdot}25}{6{\cdot}5}} = 5{\cdot}1$ inches.

TO DETERMINE WHAT DIAMETER OF STEEL SHAFT WILL MAINTAIN THE TWISTING MOMENT BELOW A REQUIRED LIMIT.

δ = twist or deflection in degrees; F = twisting force in lbs., applied at pin d (Fig. 1) at right angles to crank; R = radius of twisting force in inches; L = length between arms of twist in inches; D = diameter of shaft in inches, then

$$D = 0{\cdot}08347\sqrt[4]{\frac{FRL}{\delta}} = K\sqrt[4]{FRL}.$$

TABLE OF VALUES OF δ AND K.

$$\left(K = \frac{0{\cdot}08347}{\sqrt[4]{\delta}}\right)$$

δ	K.	δ	K.	δ	K.
0·10	0·1484	1·50	0·0755	5·00	0·0558
0·15	0·1341	2·00	0·0703	5·50	0·0545
0·20	0·1248	2·50	0·0665	6·00	0·0534
0·25	0·1180	3·00	0·0635	7·00	0·0514
0·50	0·0991	3·50	0·0612	8·00	0·0497
0·75	0·0896	4·00	0·0591	9·00	0·0482
1·00	0·0835	4·50	0·0574	10·00	0·0470

Example—

What diameter, D, of steel shaft would be required to bring the twisting moment below 0·25 degree (δ), the values of D, F, R, and L being

$\delta = 0{\cdot}25$; F = 4,000 lbs.; R = 6 ins.; L = 48 ins.

From table, K (corresponding to $\delta = 0{\cdot}25$) = 0·1180, therefore

$$D = 0{\cdot}1180 \sqrt[4]{4{,}000 \times 6 \times 48} = 3{\cdot}87 \text{ ins.}$$

Twisting Angle of Steel Shafts.

To find the angle of twist or deflection, δ, of a given shaft, the value of K is found from

$$K = \frac{D}{\sqrt[4]{FRL}}$$

and the corresponding value of δ in the table gives the required result.

Standard Conditions and Rules for the Shafts of Marine Steam Engines.

(Issued by the Board of Trade* and published by His Majesty's Stationery Office, Adastral House, Kingsway. Price 1*d.* net.)

(Abstract.)

MATERIALS FOR SHAFTING.

Ingot steel for shafts shall be generally of 28 to 32 tons per sq. in. standard quality and be such that after forging or rolling the sum of its tensile strength, in tons per sq. in., and percentage of elongation, measured on the British Engineering Standards Association test-pieces C, D, or E, shall be not less than 57.

The webs of built crank shafts may be forged or rolled from ingot steel, wrought iron, or scrap mild steel, or they may be steel castings.

The material of cast steel webs generally must be such that the tensile strength does not exceed 32 tons per sq. in., and the sum of the tensile strength in tons per sq. in. and the percentage of elongation measured on the British Engineering Standards Association test-pieces C, D, or E, shall be not less than 50.

RULES FOR THE DIAMETERS OF SHAFTS.

Turbine-driven Shafting.

1. Turbine-driven installations shall have shafts the diameters of which are not less than is given by the following rule:—

$$d = \sqrt[3]{\frac{\text{S.H.P.}}{R}} \times F.$$

Where d is the diameter of the intermediate shaft in inches;

S.H.P. is the maximum designed shaft horse-power;

R is the number of revolutions per minute at that power;

F is (1) 64 for ocean-going and home-trade ships, such as would require a No. 1 or No. 2 Certificate of the Board of Trade if carrying passengers. (2) 58 for ships making short coasting voyages or working on estuaries, rivers, lochs or lakes, such as would require a No. 3, No. 4, or No. 5 Certificate of the Board of Trade if carrying passengers.

Shafting of Reciprocating Engines.

2. Reciprocating steam-engine installations shall have shafts the diameters of which are not less than are given by the following rules:—

$$d = \sqrt[3]{\frac{D^2 \times S \times p}{f(r+2)}}.$$

Where d is the diameter of the intermediate shaft in inches;

D is the diameter in inches of the low-pressure cylinder, or the equivalent diameter where two or more low-pressure cylinders are used;

S is the stroke of the piston in inches;

* Accepted by Board of Trade, Lloyd's Register, British Corporation, and Bureau Véritas, at Conference for the Unification of Rules for the Construction and Dimensions of Shafting for Marine Steam Engines, April 16, 1923.

p is the working pressure in the boiler in lbs. per sq. in.;

r is the ratio of the swept volume of the low-pressure cylinder or cylinders to that of the high-pressure cylinder or cylinders;

is a coefficient from the following table, and has two values for each type of engine depending upon the nature of the service as defined in the foregoing paragraph.

Type of compound, triple or quadruple reciprocating engine.	Service of Ship.	
	No. 1 (1).	No. 1 (2).
(*a*) 2 cranks at 90°	1900	2100
(*b*) 2 cranks at 180°	1350	1500
(*c*) 3 cranks at 120°	2150	2400
(*d*) 4 cranks balanced	2150	2400
(*e*) 4 cranks at 90°	2100	2300

(2) Crank shafts shall be in diameter not less than $1{\cdot}05 \times d$.

(3) Thrust shafts transmitting torque shall be at the collars not less in diameter than $1{\cdot}05 \times d$. Thrust shafts may be tapered down outside the collars to the diameter d required for the intermediate shaft.

(4) Tube shafts shall be in diameter not less than $1{\cdot}05 \times d$, and any part of a tube shaft within the tube which may be exposed to sea-water shall be in diameter not less than $1{\cdot}075 \times d$.

(5) Wheel shafts of geared turbine-driven installations shall be in diameter not less than $1{\cdot}05 \times d$, but where there is only one pinion gearing into the wheel, or where there are two pinions which are set to subtend an angle at the centre of the shaft of less than 120° the diameter of the wheel shaft at the wheel and the adjacent journals shall be not less than $1{\cdot}1 \times d$. Abaft the journals the shaft may be tapered to $1{\cdot}05 \times d$.

Tail Shafts.

3. Tail shafts shall be not less in diameter than is given in the following rule:—

$$d_t = d + \frac{P}{K},$$

where,

d_t = diameter of tail shaft in inches;

d = diameter of intermediate shaft required;

P = diameter of screw propeller in inches;

K = 144 where a continuous liner is fitted;

K = 100 where a continuous liner is not fitted.

Tail shafts which run in stern tubes may have the end forward of the stern gland tapered down to a diameter at the coupling flange equal to $1{\cdot}05 \times d$.

Crank Webs of Built Shafts.

1. Crank webs of built shafts should have dimensions not less than the following:—

$$h = 0{\cdot}625 \times d$$

$$t = \sqrt{\frac{0{\cdot}12 \times d_c^2}{h}}$$

where,

d_c = diameter of crank shaft in inches;

h = thickness of web measured parallel to the axis;

t = thickness of metal around the eye-holes measured radially.

The Rules also relate to 'Bronze Liners on Shafts' and 'Coupling Flanges and Bolts.

British Standard Specification for Shafting for Marine Purposes.

See No. 3021—1922.

Fitting Oil Snap-Rings on Shafts.

Some shaft bearings are made with snap-on sling rings, instead of wipers, to throw the oil off the shaft at a point inside the housing, and thereby prevent its creeping out of the bearing ends along the shaft. These snap-on rings are generally slipped on the shafts before they are laid into the bearings, but it occasionally happens that the shaft must be laid in first and the

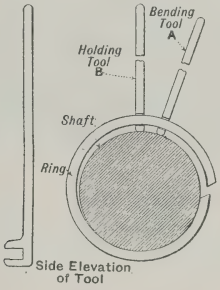

FIG. 3.

rings snapped on afterwards. To make the rings 'hug' the shafts, the tools shown in fig. 3 serve the desired purpose satisfactorily. The ring is held back with the holding tool B and then by pushing forward on the bending tool A, the ring can be made to assume a smaller circular form. The rings usually have enough temper to make them spring tightly against the shaft when the tools are removed. The tools may be made from flat stock by just filing out for the 'notch,' or they may be made from round stock by welding the grip lugs on.

(*'Power.'*)

Flexible Couplings.

Flexible couplings are now being used in all cases where it is not possible to ensure shafting being exactly in line.

Experiments over a large number of factories and works have shown that the power absorbed by shafting forms quite a large percentage of that generated. This loss is chiefly due to malalignment, and can be saved by introducing suitable flexible couplings; the same remark also applies

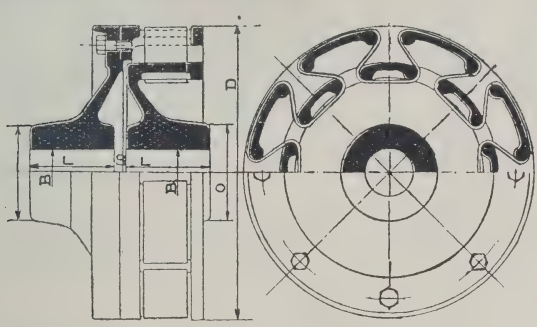

FIG. 4.

in the case of two machines whose shafts are coupled together, and apart, of course, from the actual loss of power sustained, trouble and expense is entailed due to the unnecessary stresses in shafting and bearings.

The flexible shaft coupling shown by fig. 4 is designed generally to absorb shocks and stresses, and for taking up malalignment and wear in bearings.

The coupling, fig. 4, consists of four parts :

(*a*) The outer disc, which has a suitable boss to take the shaft of the driving member.

(*b*) The belt ring, which is secured to the outer disc.

(*c*) The inner half, which has a suitable boss for taking the shaft of the driven member.

(*d*) A special cotton belt, which passes alternately around the lugs on the inner half and on the belt ring, securing together the two halves of the coupling.

The outer disc can be taken apart without removing the belt. A special advantage of the arrangement is that one shaft is electrically insulated from the other. The coupling, however, is not suitable for reversing drives.

Among the many applications of this type of coupling may be mentioned the following :—

For generators driven by steam, gas, oil, and petrol engines, or motors ; for motor-driven centrifugal fans ; for direct connected motor-driven shafting in textile and other mills ; for motor-driven rolling-mills ; for direct connection between motors and machine tools, and for connecting one length of shafting with another.

SECTION XX

PART V

SPRINGS.

HELICAL.

If r = mean radius of spring, in inches, measured from axis to centre of wire; d = diameter, in inches, of wire, if *round* in section; h and b = depth and breadth respectively, in inches, of wire, if *rectangular*; b = breadth and depth, if *square*; n = number of coils of which spring consists; c = coefficient or modulus of transverse elasticity of wire, in lbs. per square inch; W = any load, in lbs., not exceeding the greatest safe load; Δ = corresponding extension or compression, in inches; W_s = greatest safe *steady* load, in lbs.; Δ_s = greatest safe corresponding extension or compression, in inches; f = greatest safe shearing stress per square inch, in lbs.; then

$$\Delta = \frac{W n r^3}{c d^4} 64, \qquad \text{or,} \quad W = \frac{\Delta c d^4}{64 n r^3}, \quad \text{for } \textit{round} \text{ wire}$$

$$\Delta = \frac{W n r^3}{b^3 h^3} 6\pi, \qquad \text{or,} \quad W = \frac{\Delta c \dfrac{b^3 h^3}{b^2 + h^2}}{6\pi n r^3} \quad \text{for } \textit{rectangular} \text{ wire}$$

$$\Delta = \frac{W n r^3}{c b^4} 12\pi, \qquad \text{or,} \quad W = \frac{\Delta c b^4}{12\pi n r^3}, \quad \text{for } \textit{square} \text{ wire}$$

$$\Delta_s = \frac{f n r^2}{c d} 4\pi, \qquad \text{and,} \quad W_s = \frac{f d^3 \pi}{r\, 16}, \quad \text{for } \textit{round} \text{ wire;}$$

$$\Delta_s = \frac{f n r^2}{c \dfrac{b h}{\sqrt{b^2 + h^2}}} \left(\frac{\pi}{2}\right)^3 \frac{3}{\sqrt{2}}, \text{ and,} \quad W_s = f \frac{\dfrac{b^2 h^2}{\sqrt{b^2 + h^2}}}{r} \left(\frac{\pi}{4}\right)^2 \frac{1}{\sqrt{2}}, \quad \text{for } \textit{rectangular} \text{ wire}$$

$$\Delta_s = \frac{f n r^2}{c b} \left(\frac{\pi}{2}\right)^3 3, \qquad \text{and,} \quad W_s = \frac{f b^3}{r} \left(\frac{\pi}{4}\right)^2 \frac{1}{2}, \quad \text{for } \textit{square} \text{ wire.}$$

$$\text{Greatest safe sudden load} = \frac{W_s}{2}; \qquad \text{Resilience} = \frac{W_s \Delta_s}{2}$$

$\frac{1}{64} = \cdot0156$; $6\pi = 18\cdot85$; $\frac{1}{6\pi} = \cdot0531$; $12\pi = 37\cdot70$; $\frac{1}{12\pi} = \cdot0265$; $4\pi = 12\cdot57$;

$\frac{\pi}{16} = \cdot196$; $\left(\frac{\pi}{2}\right)^3 \frac{3}{\sqrt{2}} = 8\cdot22$; $\left(\frac{\pi}{4}\right)^2 \frac{1}{\sqrt{2}} = \cdot436$; $\left(\frac{\pi}{2}\right) 3 = 11\cdot63$; $\left(\frac{\pi}{4}\right)^2 \frac{1}{2} = \cdot308$.

The value of c for steel in lbs. per square inch may be taken as 16,000,000. The greatest safe value (f) which is certain not to impair the elasticity of the spring by frequent repetition may be taken at 50,000.

From the formula $W_s = \frac{\cdot196 f d^3}{r}$, if $f = 50{,}000$, we get,

$$d = \sqrt{\frac{W_s r}{\cdot196 f}} = \sqrt[3]{\frac{W_s 2r}{\cdot392 f}} = \sqrt[3]{\frac{W_s 2r}{19{,}600}}; \quad \text{Board of Trade rule, } d = \sqrt[3]{\frac{W_s 2r}{8{,}000}}$$

A spring with its mean diameter small as compared with the size of the bar will allow a higher stress with less set than one of larger mean diameter; size of bar being the same, a spring of small diameter may safely stand higher stress than one of large diameter; springs of too small diameter compared with size of bar are so injured in coiling as to weaken the steel; the ratio of mean diameter of spring to diameter of bar should never be less than 3. For a good grade of steel the following values have been found safe:

Ratio of Mean Diameter to Diameter of Bar.	Safe Torsional Stress.	
3	112,000	Bars less than $\frac{1}{4}$ in. in diameter.
8	85,000	
3	110,000	Bars $\frac{7}{16}$ in. to $\frac{3}{4}$ in in diameter.
8	80,000	

Ratio of Mean Diameter to Diameter of Bar.	Safe Torsional Stress.	
3	105,000	Bars $\frac{13}{16}$ in. to $1\frac{1}{4}$ in. in diameter.
8	75,000	

For extension springs the value of stress is only two-thirds these values.

(Contributed by R. A. Sturgeon, Assoc.M.Inst.C.E.)

Table of Safe Loads and Scales.

The stresses from which the safe loads are calculated are given for each size of wire. The scale—i.e. the ratio of load to deflection produced—is based on a single coil spring. By dividing the figure given in the table by the number of coils in the spring, the load required to extend or compress the spring 1 in. is obtained. The value of G is assumed to be 12,000,000 lbs. per sq. in.

Multiplying Constants.

1. For compression springs with little variation of load multiply *Safe Loads* by 1·25.

2. For Springs, especially tension springs subjected to considerable variation of load suddenly applied, multiply *Safe Loads* by 0·67.

3. For Square Wire Springs where the Side equals the diameter given in the table—multiply

Safe Load by 1·06
Scale by 1·5

4. For Brass Wire Springs (round) multiply the Scale by 0·42. (Only for *Hard* Brass.)

Note.—In getting out Compression Springs allow for the fact that one coil at each end is idle. These two coils do not affect the Scale, but do affect the closed length.

PHOSPHOR-BRONZE SPRINGS.

The formulæ adapted for phosphor-bronze wire such as is manufactured by the Phosphor-Bronze Smelting Company, of Philadelphia, are as follows :—

$$W = \frac{7{,}000\, d^3}{D - d}; \quad F = \frac{8\, P\, (D-d)^3}{6{,}200{,}000\, d^4}.$$

When P = W, then

$$F = \frac{7\, (D-d)^2}{775\, d}$$

W = carrying capacity, in lbs. ; d = diameter of wire, in ins. ; D = outside diameter of coil in ins. ; F = deflection in one coil, in ins. ; P = load, in lbs.

These formulæ for springs of all diameters, ranging from d = No. 10 B. & S. gauge to $d = \frac{5}{8}$ in., are accurate within 10 per cent. They apply equally well to tension springs wound closely without initial tension.

(*H. R. Gilson.*)

CLOCK TYPE SPRINGS.

(1)

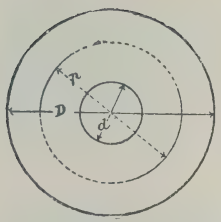

FIG. 1.

Let
d = diameter of inmost coil = spindle + t ; D = diameter of outer coil = barrel − t ; b = breadth of spring steel ; t = thickness of spring steel ; L = total length ; I = moment of inertia of section ; n = number of coils when unwound ; n' = number of coils when wound ; s = turns from unstrained state ; E = coefficient of elasticity ; a = total angle of wind ; p = diameter of inner coil unwound, or of outer coil wound ; M = moment of spring in inch pounds.

For D = 3d the following obtains :—

$$tn = \cdot1273\,D; \qquad d = 0\cdot33\,D;$$

$$t = \frac{\cdot0787\,D}{n'-n}; \qquad n = \frac{\cdot1273\,D}{t}; \qquad n' = \frac{\cdot206\,D}{t};$$

$$I = \frac{bt^3}{12}; \qquad L = \frac{\cdot3491\,D^2}{t}; \qquad \text{or} \quad L = n \times 2\cdot7416\,D; \qquad a = 2\pi s;$$

$$M = \frac{Ebt^3a}{12L}; \qquad D = \sqrt{\frac{\cdot000859\,M\,(n'-n)^4}{bs}}; \qquad p = \sqrt{\tfrac{1}{2}(D^2+d^2)}.$$

d = usually 30t. For any spiral, $L = \frac{N}{2}(C+c)$, C and c being the circumferences of extreme coils. Maximum practicable, D = 160t.

(2)

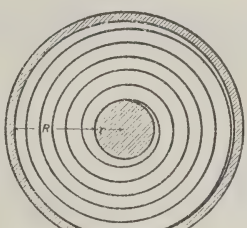

FIG. 2.

l = length of spring ; b = breadth of spring : = thickness of spring : each in inches. E = Young's modulus of elasticity in lbs. per sq. in. ; F = safe tensile strength of material in lbs. per sq. in. ; N = number of turns spring is capable of taking. R = radius of box containing spring ; r = radius of arbor : each in inches. T = maximum torque of spring.

$$= \frac{F}{E} \cdot \frac{(R+r)(R+3r)}{R-r}; \qquad b = \frac{6E^2}{F^3} \cdot \frac{T(R-r)^2}{(R+r)^2(R+3r)^2};$$

$$l = \frac{\pi E}{4F} \cdot \frac{(R-r)^2}{R+r}; \qquad N = \frac{E}{4F} \cdot \frac{(R-r)^3}{(R+r)^2(R+3r)}.$$

For steel, E = 32,000,000 ; F = 224,000 ;

therefore

$$t = \cdot007\,\frac{(R+r)(R+3r)}{R-r}, \qquad b = \cdot547\,\frac{T(R-r)^2}{(R+r)^2(R+3r)^2},$$

$$= 112\cdot2\,\frac{(R-r)^2}{R+r}. \qquad N = 35\cdot7\,\frac{(R-r)^3}{(R+r)^2(R+3r)}.$$

(*J. St. Vincent Pletts :* '*The Engineer*,' *July* 18, 1913.)

VOLUTE FLAT SPRINGS.

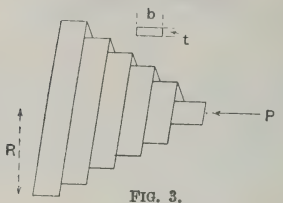

FIG. 3.

If

P = carrying capacity of spring in lbs. = greatest safe *steady* load; S = safe stress in bending, in lbs. per sq. in.; b = breadth of spring metal; t = thickness of spring metal; R = radius of spring at base; L = length of spring; G = torsional modulus of elasticity; S_s = safe shearing stress in lbs. per sq. in.; Δ = deflection of spring in ins.; C for various ratios of $\frac{b}{t}$ is as follows:

$\frac{b}{t}$	1	2	4	8
C	3·56	3·50	3·35	3·21

then,

$$P = \frac{2Sbt^2}{9R}\ ;\quad \Delta = \tfrac{1}{2}CR^2L\frac{(b^2+t^2)P}{Gb^3t^3} = \tfrac{1}{2}CRL\frac{(b^2+t^2)S_s}{Gb^3h},$$

the torsional modulus of elasticity for steel being 12,600,000.*

See also 'Kent's Mechanical Engineers' Handbook.' (New York: John Wiley & Sons, Inc.; London: Chapman and Hall, Ltd.)

CONICAL ROUND WIRE SPRINGS.

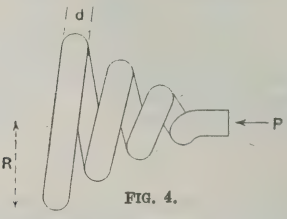

FIG. 4.

If

d = diameter of wire; H = solid height of spring, assumed to equal d × number of coils, then,

$$P = \frac{\pi Sd^3}{16R} = \cdot 196\frac{S_sd^3}{R};$$

$$\Delta = \frac{16PLR^2}{\pi Gd^4} = \frac{RLS_s}{Gd};$$

$$L = 1\cdot 571\frac{H}{d}(D_1 + D_2).$$

If

D_1 = mean diameter of largest coil; D_2 = mean diameter of smallest coil; p = average horizontal pitch of coils; d = diameter of wire,

then,

$$\Delta = 0\cdot 00332\frac{D_1^3 - D_2^3}{pd};\quad P = 31{,}400\frac{d^3}{D_2},$$

the torsional modulus of elasticity for steel being 12,600,000.*

See also 'Machinery Handbook.' (New York: The Industrial Press; London: The Machinery Publishing Co., Ltd.)

* See Semi-Steel, p. 184.

Heat Treatment of Springs.

Experiments made by the Automatic and Electric Furnaces, Limited, show that springs heated to 800 degrees and afterwards tempered to 350 degrees give the best results. Overheating is shown to be detrimental; springs which are heated to 900 degrees and quenched, then reheated to 800 degrees and tempered at 350 degrees, show that the bad effects of overheating are not neutralised by reheating to 800 degrees and requenching. These effects can be neutralised by thoroughly annealing after the first overheating and then by reheating to the correct temperature and quenching.

A spring that has not been overheated, and that has been correctly tempered, can be loaded up to within 5 per cent. of its breaking point without showing any set after the first loading.

Handy Kink for Making Spiral Springs.

Take a piece of fibre about 2 by 6 ins. and bore four or five holes in one end, ranging in size from $\frac{1}{8}$ to $\frac{3}{8}$ in., as in fig. 5. Near the large holes bore several small ones, say $\frac{1}{16}$ in. in diameter. By using nails or pieces of small rod, any size spring can be made, according to the size of the holes.

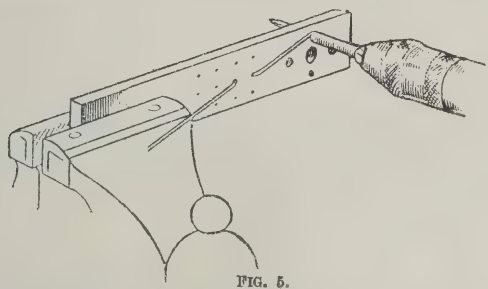

FIG. 5.

Put the block in a vice and thread the spring wire through the holes to give it tension. Take a nail the size of the spring you want to make, cut the head off, and put it into the hole where it fits best. Wrap a few turns of the wire around the nail, and grip the wire and nail in an ordinary brace, as in the figure. Then simply wind the wire around the nail until the desired length of spring is obtained. (*J. W. Fager, 'Power.'*)

Winding a Compression Spring.

Small music wire compression springs can be easily made by the following method. Having selected a mandrel A, fig. 6, the exact diameter of the interior of the desired spring, and wire B, obtain a piece of hard wood C and bore a hole in it in which the mandrel will fit, as shown in the illustration. Within $\frac{1}{32}$ inch from this hole bore another hole, the size of the wire to be used for the spring. Place the mandrel in the chuck of the lathe, slip the piece of wood over the mandrel, and insert the wire in the smaller hole, pushing it through until its end catches in the jaws of the chuck. Now press the piece of wood against the jaws of the chuck and commence winding the spring, first by pulling on the lathe belt, and then by throwing on the power when the coiling operation is well started. During the winding operation, the piece of wood should be pressed firmly against the coils so that the spring will have the appearance of being close wound. When the completed spring is removed from the mandrel, it will elongate or expand, thus forming a compression spring that is the size of the mandrel on which it is wound.

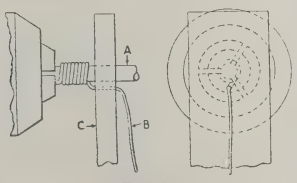

FIG. 6.

If, instead of leading the wire through a small hole as described, a notch is cut in the hole which fits over the mandrel, and the wire fed through this, the inside diameter of the spring will be smaller than the outside diameter of the mandrel. To make the spring a loose fit on the mandrel, the wire should be led through a small hole located at a greater distance from the large hole. If the spring is straightened out by pulling it off from the mandrel, the wire will be badly kinked, but if re-wound by the

methods described, a good spring will be produced. To remove the strains in the wire spring that result from the winding operation, it should be heated carefully, if made from steel, until it is a uniform blue colour. If the spring is made of phosphor-bronze or brass wire, it should be covered with tallow or beeswax and heated until it smokes; this will remove the strains, so that it will maintain its form. (*J. H. B.*, '*Machinery*.')

METAL CUTTING MACHINES.

LATHES.

With a cutting angle of 80° for cast iron (tool angle 75°) and of 70° for soft steel (the best cutting angles in practice), the horse-power needed at the point of the tool is about 2 h.p. per pound of chips per minute. To this must, of course, be added the power needed to drive the tool light, which, in the case of light cuts, is a large proportion of the whole, and is the main reason why a heavy cut and a slow speed are more economical of power than a light cut at a higher one. Where the chips come off in the same shape and fashion, and the tools are equally sharp, the net horse-power expended in the actual cutting operation is practically the same per pound of metal removed whether a light or a heavy cut is taken. The power to be provided will, of course, depend upon the heaviest cut which the tool is to take. This will generally be heavier in a turret lathe than in a common lathe operating on work of the same diameter.

For the common lathe the heaviest cut is $\frac{1}{40}$th of the height of the centres in depth, and the traverse is $\frac{1}{160}$th of the same height. The area cut is then $\frac{h^2}{6,400}$, where h is the height of the centres. The speed of cutting may be in feet per minute,

$$\text{For soft steel, } v = \frac{10}{\sqrt[3]{a}}. \qquad \text{For cast iron, } v = \frac{3{\cdot}5}{\sqrt[3]{a}}.$$

where v is the cutting speed in feet per minute, and a is the area of cut in square inches.

Keener tools should be used on a material like copper than on steel, and keener on steel than on cast-iron.

In regard to the proper proportioning of the step-pulley and change-gears, the highest speed should be that enabling the tool to give its maximum possible output on the smallest diameter which it is profitable to turn in the lathe, and this may be a diameter of one-eighth the height of centres. The lowest speed should be such that the maximum output is also attained on the maximum diameter which can be swung on the lathe. The geometric ratio between successive speeds should be 1·08 in the case of a 6-inch lathe and 1·24 in the case of a 72-inch lathe. That is to say, if R be the maximum of revolutions per minute provided for and r the smallest, then, in the case of a 6-inch lathe, $R = r(1{\cdot}08)^n$, where $n + 1$ is the total number of speed changes.

The highest and lowest Spindle Speeds and their ratio.—These data are fundamental to the design of the fast headstock, and the following figures, rationally deduced, have been confirmed by practice: —

Height of centres . .		6 ins.	12 ins.	18 ins.	36 ins.	60 ins.	
Spindle speeds for carbon steel lathes	Greatest .	300	150	102	50	30	Ratio
	Least .	6	3	1·7	0·5	0·16	
		50	50	60	100	180	
Spindle speeds for high-heat steel lathes	Greatest .	600	300	200	100	60	Ratio
	Least .	80	10	4	1	0·5	
		10	30	50	100	120	

The Belt drive.—To enable them to transmit the great powers now required, much higher belt speeds have become necessary. Speeds through the air of 2,000 ft. or 3,000 ft. per min. are now used, and unduly wide belts avoided. The efficiency of the belt drive is also improved by using large pulleys running at moderate speeds, rather than small pulleys running at very high rates of revolution.

A simple rational formula for the power required for actual cutting when operating with ordinary high-speed steel on mild steel is :—

$$\text{Cutting HP} = \frac{\text{Force} \times \text{speed of cutting}}{33{,}000}.$$

The force for mild steel is 90 tons per square inch and the standard cutting speed is $\frac{10}{\sqrt{a}}$ where a is the area of cut (cut × traverse) in square inches.

$$\text{Thus C.HP} = \frac{2240 \times 90 \times a}{33{,}000} \times \frac{10}{\sqrt{a}} = 60\sqrt{a}.$$

For standard lathes the test cut in terms of the height of centres is

$$\frac{h}{40}, \text{ and the traverse is } \frac{h}{160}, \text{ or } a = \frac{h^2}{6{,}400}$$

$$\text{Then C.HP} = 60\sqrt{a} = 60\sqrt{\frac{h^2}{6{,}400}} = 0{\cdot}75\,h.$$

Adding 10 per cent. say for friction in the journals, gears, etc., then gross HP = 0·83 h.

(Nicolson & Smith.)

High-Speed Lathe Centres.

Owing to trouble experienced with carbon steel centres on repetition work, an experiment was made by the Ready Tool Co., of U.S.A., with the use of high-speed steel centres. These centres were used on the same machines and for the same work as carbon-steel centres, they showed no signs of either burning or wearing after five weeks of hard usage, and as a result it was definitely decided to put them on the market.

Experiments have shown that on lathe work at both high and low speeds the life of high-speed centres is easily ten times that of carbon-steel centres. In grinding machines, high-speed centres also seem to stand the wear of the abrasive which gets into the cutting compound and deteriorates the carbon-steel centres very rapidly.

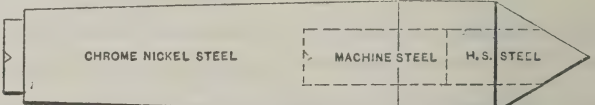

Fig. 1.

The centres, being made from solid high-speed steel, were, of course, expensive, but by welding the front or wearing end of the high-speed steel centre to a chrome-nickel steel shank, a satisfactory centre can be made at a comparatively low cost. These centres are shown by fig. 1 ; the object in designing the centres was to reduce the first cost, especially in large sizes, and still retain all the advantages of a high-speed steel centre.

The centre consists of a chrome-nickel steel shank having a high-speed steel point. This point is welded to a machine-steel extension piece to provide an unusually deep seat in the shank and ensure holding the point securely. The hole in the shank is reamed slightly tapering, and the point or plug is ground, after hardening, to the same taper as this hole. In assembling the plug and shank, the latter is first heated to about 1100° or 1200° F., and then the plug is forced into the hole under a heavy pressure, after which the shank is cooled by plunging it into cold water. As a result of this combination shrinkage and force fit, the plug or centre is gripped very tightly by the shank.

Lathe Tool Holders.

It is rarely possible to hold a too or cutter securely by a plain parallel shank or stem fitting alone, without any sort of screw or binding clamp. Fig. 2 shows a tool holder made by Sir W. G. Armstrong, Whitworth & Co., Ltd., Manchester, for their railway wheel lathes. The tool has a head *A*, about 1½ inches in diameter, which is tapered slightly to provide for front clearance.

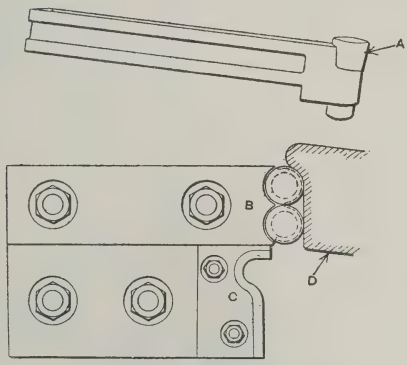

Fig. 2.

The stem is cylindrical and a tight fit in the holder. The top of the head is dished slightly to give the required rake. In machining the holder, the end is countersunk to fit the head, after which the front portion is cut away; this leaves a close-fitting supporting wall at the back of the cutter. When the cutting edge is dulled, the tool *A* is simply loosened and turned around far enough to bring a new cutting edge into position. When the entire edge has become dull, the tool is re-ground.

PLANING MACHINES.

Vickers' Patent Automatic Reversing Drive.

In this system, fig. 3, as applied to a planer, the motor itself reverses and is directly geared to the driving screw or rack-wheel of the machine. There are no driving pulleys to reverse, and the inertia of the driving system is much reduced, permitting quick reversal without the excessive waste of energy shown by a power diagram of the usual type of belt machines. There are no belts to wear. The cost of belts averages 30*l.* to 40*l.* per annum on belt-driven planers of large size. The speed of cutting can be instantly varied between the limits of the slowest cut and of the quick return. Thus, in a planer having slowest cutting speed 15 ft. per min., and (constant) quick return 60 ft. per min., the cut can be varied from 15 ft. to 60 ft. per min. by small intervals, and without altering the quick return speed, by simply turning the handle of the speed controlling switch to the proper position. The speed of the return stroke can be varied in a similar manner. The cutting speed can be instantly suited to the material from the hardest steel to softest steel and wrought iron, thus increasing the general output of the machine. The tool will plane accurately up to a line.

VICKERS' PATENT AUTOMATIC REVERSING DRIVE.

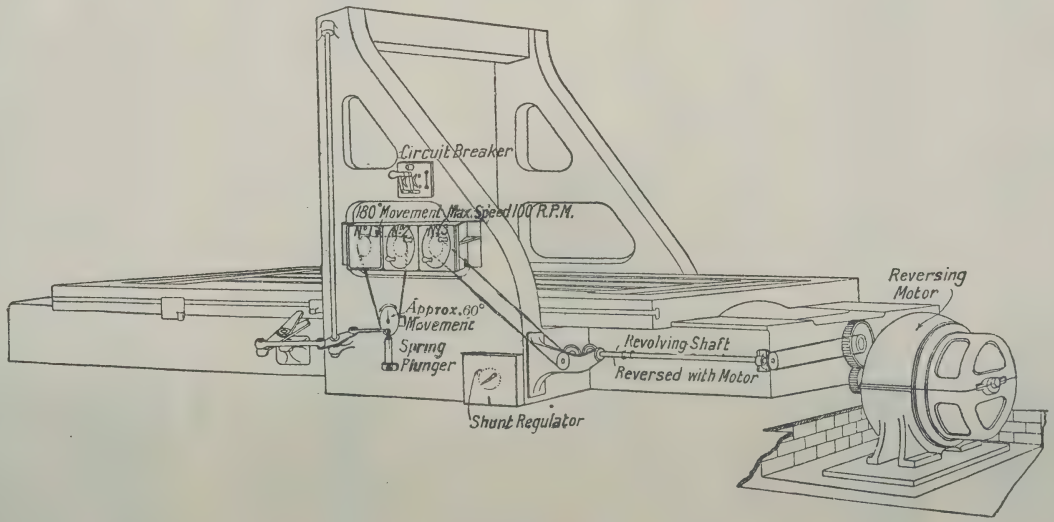

FIG. 3.

The following is a list of speeds of cutting and return stroke in use with planers which have been converted to this system of drive :—

Size of Planer.	Cutting Speeds.	Return Speeds.	No. of Tools.	Horse-power of Motor.
Feet.	Ft. per Min.	Ft. per Min.		
3 × 3 × 20	30/120	120/30	3	10
4 × 4 × 12	30/120	120/30	3 or 4	15
5 × 5 × 12	30/120	120/30	4	20
6 × 6 × 14	25/100	100/25	4	25
7 × 7 × 18	25/100	100/25	4	30
8 × 8 × 16	20/80	80/20	4	40
9 × 9 × 20	15/60	60/15	4	45
10 × 10 × 20	15/60	60/15	4	45
*12 × 12 × 24	10/40	40/10	Up to 8	50

* Armour-plate planing machines.

PLANING MACHINE TESTS.

Material.	Cutting Speed. Feet per Minute.	Depth of Cut.	Feed.	Authority.
		In.	In.	
Steel slabs . . .	25	$\frac{1}{2}$	$\frac{1}{8}$	Armstrong-Whitworth, using A.W. Steel.
Steel horn blocks .	35	$\frac{1}{2}$	$\frac{1}{8}$	Armstrong-Whitworth, using A.W. Steel.
Hard cast iron . .	40	$\frac{1}{4}$	$\frac{1}{8}$	Richard Hornsby & Sons, Ltd.
Cast iron . . .	36	$1\frac{1}{2}$	$\frac{1}{7}$	Armstrong-Whitworth.
Cast iron . . .	55	$\frac{1}{2}$	$\frac{3}{16}$	Armstrong-Whitworth.

PLANING SPEEDS AND FEEDS.

Material.	Cutting Speed. Ft. per Min.	Feed Ins. per Stroke.	Depth of Cut. Ins.
Roughing Cuts.			
Cast iron	37–48	$\frac{3}{16}$	$\frac{7}{16}$
Cast steel	28–48	$\frac{5}{32}$	$\frac{1}{4}$
Machine steel	28–48	$\frac{5}{32}$	$\frac{1}{4}$
NOTE.—Leave $\frac{1}{32}$ in. of metal for removal by subsequent cuts. When so set, the tools tend to dig in and actually leave about 0·026 in. of surplus stock.			
Straightening Cuts.			
Cast iron	45	$\frac{3}{16}$ to $\frac{1}{4}$	0·018
Cast steel	45	$\frac{1}{8}$	0·018 to 0·021
Machine steel	45	$\frac{1}{8}$	0·018 to 0·021
Finishing Cuts.			
Cast iron	28–35	$\frac{1}{4}$ to $1\frac{1}{2}$	0·003 and 0·001
Cast steel	45	$\frac{1}{32}$	0·004
Machine steel	45	$\frac{1}{32}$	0·004
NOTE.—For cast iron, it is good practice to divide the work up into two operations, taking off 0·003 in. with the first cut and 0·001 in. with the second cut. This prevents a tendency for the tool to dig in at the high spots.			

SPEED TABLE FOR PLANING MACHINES.

(Bateman's Machine Tool Co. Ltd.)

Size of Planer.	Length of Stroke taken.	Time of 10 Cycles.	No. of Feet in 10 Cycles.	Average Speed.	Maximum Speeds. Ft. per min.	
	Ft. Ins.	Min. Secs.		Ft. per Min.	Out.	Re-turn.
24 ins. by 24 ins. by 6 ft.	6 3½	1 8	126	111	80	225
30 ins. by 30 ins. by 8 ft.	8 0	4 20	160	37	22	218

42 ins. by 42 ins. by 20 ft.	22 6	6 39	450	68	45	145
42 ins. by 42 ins. by 14 ft.	14 0	3 56	280	71	50	155
42 ins. by 42 ins. by 12 ft.	11 0	2 36	220	84	58	175
48 ins. by 48 ins. by 8 ft.	8 0	2 4	160	77	52	160
60 ins. by 60 ins. by 12 ft.	12 0	6 0	240	40	25	150
(With three-speed gear-box)	12 0	3 50	240	62½	42	150
	12 0	2 50	240	85	60	150
72 ins. by 72 ins. by 16 ft.	16 0	7 40	320	41	25	110
(With three-speed gear-box)	16 0	5 40	320	56	39	110
	16 0	4 50	320	66	50	110

For taking the roughing and straightening cuts it is usually found that high-speed steel is the most satisfactory material, owing to its greater productive capacity ; but where considerable accuracy and perfection of finish is required in performing the final planing operations, far more satisfactory results will usually be obtained by making the cutting tools of carbon steel, because this material can be ground to a keener edge, and experience has shown that the tools retain this edge longer and are thus able to produce a smoother and more accurate finish on the work.

MILLING MACHINES.*

One of the chief points is to make the cutters of such shape that all the fitting surfaces and cutting edges can be easily and accurately ground. In fig. 4 an ordinary grooving cutter is shown so designed. It will be noticed that the hole is chambered out so that the cutter fits the spindle at the two narrow surfaces, A and A′, only. These surfaces can be more easily ground to standard size than could a bearing the full width of the cutter. After the hole has been accurately finished it is an easy matter to mount the cutter on a mandrel and grind the surfaces BB and B′B′, and also the cutting edges, CC, C′C′, and DD all at the same setting, as indicated in fig. 4. Nothing now remains to be done but to back off the teeth in the way indicated in figs. 5 and 6. Such a cutter, when mounted on a true spindle, provided with a solid collar, against which the cutter is held, is self-setting and accurate.

In determining the correct angle for the face of the teeth, the diameter and shape of the cutter should be taken into account. For small-sized cutters it will, in order to obtain a strong shape, generally be found best to make the faces truly radial, as shown in figs. 4, 5, and 6. This also is more convenient when the cutter is to have teeth both on the sides and periphery. Cutters with the teeth so formed have worked upon both wrought and cast iron perfectly well, and at the same time they are not so liable to seize hold and bite into the work as cutters which have the faces of their teeth undercut. The pitch of the teeth is, again, partly determined by the diameter and class of cutter. In those cutters which are cut at the sides, the pitch at the circumference has often to be made wider than is advisable, in order to give clearance room for the emery wheel

* Abstract of a paper read before the Manchester Association of Engineers.

when grinding the converging side teeth (see fig. 6). A pitch of from $\frac{5}{16}$ inch to $\frac{3}{8}$ inch will usually be found to give good results. In all except very narrow cutters it is advisable to cut the teeth on the periphery spirally. This ensures a smoother action of the machine and produces better work. In deciding whether to make the cutters right- or left-hand spirals, attention should be paid to the direction in which they are to revolve. For example, in a vertical machine whose spindle revolves to the right hand, as in an ordinary drilling machine, the cutters should be cut

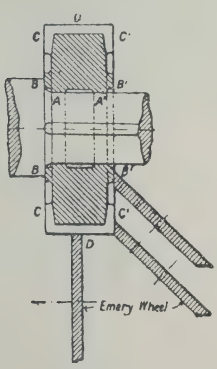

FIG. 4.

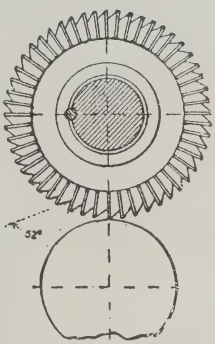

FIG. 5.

with a left-hand spiral. This has the effect of forcing the work down on to the table and the spindle up against its end bearings, as the cutter and the work act as a screw and a nut. In cutters of small size high-class tool steel is most suitable, although great care is required in heating it gradually and evenly. The bottom of the spaces between the teeth should be slightly rounded, and the keyways made semicircular, in order to avoid starting-places for fracture.

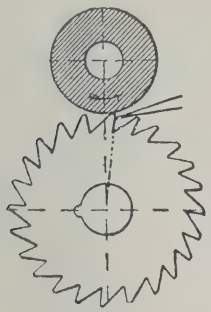

FIG. 6.

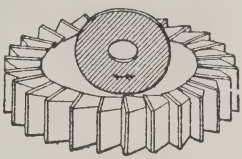

FIG. 7.

For cutters of larger sizes and strong sections Howell's case-hardening steel may be used with great advantage.

Too great stress cannot be laid upon the necessity of keeping milling cutters sharp, and both machines and cutters in such a condition that the cutters shall run true. In grinding milling cutters it is essential that the spindle and emery wheel of the grinding machine should run true and be accurately balanced, as, owing to the high speeds at which they are run, it is clear that any inaccuracy in these respects is highly detrimental. In order to prevent the emery wheel from

glazing, it is necessary to keep it perfectly free from oil or perspiration, and care should be taken not unduly to force the emery wheel against the work, as excessive pressure rapidly generates heat, which not only softens and glazes the emery wheel, but also draws the temper of the thin edges of the cutter, often without showing any discoloration on the edge just ground. For general cutter grinding the emery wheels should be fairly coarse and free-cutting, otherwise they are apt to soften the cutter, which may be known by a fine blue burr, to be seen on the faces of the teeth, the metal along this line being softened. For ordinary-sized cutters an emery wheel $2\frac{1}{2}$ inches in diameter by $\frac{5}{16}$ inch or $\frac{1}{4}$ inch wide will be found most suitable, the speed of which may vary from 3,000 to 4,500 revolutions per minute, but either too fast or too slow a speed will cause the wheel to burn and soften the cutter. The finishing cut should be very small in amount, especially in cutters of large diameter, otherwise the wear in the diameter of the emery wheel will materially affect the height of the cutter teeth, those last ground being the highest.

For general work, in which ordinary cylindrical cutters can be used, cutters of small or medium size, say up to $3\frac{1}{2}$ inches in diameter, will be found to possess important advantages.

The plain cylindrical cutter is the cheapest and most effective wherever it can be used.

Speed of Milling Cutters.

Table I. shows examples taken from everyday practice, working on wrought-iron forgings.

TABLE I.

Diameter of Cutter.	Depth of Cut.	Width of Cut.	Revolutions of Cutter per Minute.	Cutting Speed in Feet per Minute.	Feed in Inches per Minute.

The above table gives particulars of a range of cutters suitable for heavy roughing work, and also corresponding fine pitch cutters used for light milling.

(*P. V. Vernon* (*Alfred Herbert & Co.*))
(*Paper read before the Manchester Association of Engineers*, 1912.)

Experiments to determine the effect of cutting speed on the life of a milling cutter were mentioned by E. Buckingham in a discussion on a paper on milling that was read recently before the American Society of Engineers. Tests were made at speeds of 70 and 80 feet per minute with high-speed steel cutters on small nickel-steel forgings. Very consistent results showed definitely that at 70 feet per minute the cutters would mill twice as many pieces as when running at 80 feet per minute. Therefore two cutters exactly similar, except that one has 21 and the other 24 teeth, would show a great difference in their life between grindings if each were set to remove the same amount of material in the same time. Under the conditions mentioned above the 24-tooth cutter would mill twice as many pieces before regrinding were necessary. The author of the original paper referred to experiments conducted with spiral milling cutters. One of the cutters experimented with was of double spiral type, in which successive teeth are of opposite spiral hand. The results when compared with those obtained from a spiral cutter with teeth all of one hand, showed that with the double spiral there was a saving of from 20 to 30 per cent. in the power required. (*'Power.' February* 16, 1922.)

The cutting speed will, when tapping and screwing with carbon steel tools and copious streams of lubricant, be about 10 ft. per minute.

A Milling Cutter for Copper.

The diameter of the cutter (fig. 9) should be of such proportions as will allow the placing of eighteen teeth of 1-in. pitch upon a 6-in. diameter circle. This will give excellent results, and is the result of a series of exhaustive tests.

Each tooth should be hacked off slightly on either side, as shown shaded at A, and have a rake angle of about 10°.

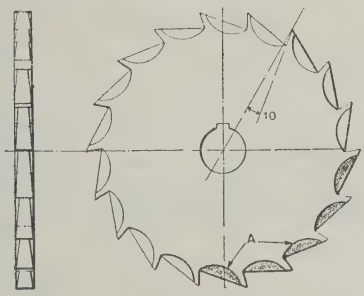

FIG. 9.

Should a cutting lubricant be found to be necessary, a quantity of lard oil, thinned with turpentine, is recommended. (*Mechanical World*, *April* 3, 1925.)

BROACHING.

Recently the finishing of holes, oil gutters, keyways, etc., by broaching has received considerable attention. Any class of material appears to lend itself to this process provided the broach is of suitable design. Broaches under 1½ ins. diameter are frequently made of high-speed steel containing from 14 per cent. to 18 per cent. tungsten. Such steel, however, is hard throughout and likely to fail under shock. For this reason, some firms make their broaches entirely of vanadium steel, which contains neither tungsten nor chromium. This steel is hardened at 750° C. and quenched in oil and tempered at 420° C. For general work a mild steel containing about 0·15 per cent. carbon, carburised at 900° C., reheated to 800° C. and dipped in water has given very satisfactory results. The reheating before quenching gives a tough core. For broaching hard steel, a mild steel containing from 2 per cent. to 3 per cent. nickel and about 0·14 per cent. carbon, carefully case-hardened, reheated to 770° C. and quenched in whale oil, has proved suitable. In making a broach, choose a bar with at least ¼ in. excess in diameter of the finished broach, so as to avoid small surface cracks and skin stresses. Broaches above 2 ins. diameter are frequently built up, in which case the teeth are formed on hardened steel rings, and these are securely mounted on a mild steel core. The teeth of the broach should be periodically examined when in use. Should any of these be chipped or dulled, these must have the cutting edge restored. Should a tooth break it must be ground down and the cut distributed amongst the next four teeth or so.

In the case of white metal an accurate hole and fair finish may be obtained with a broach having fine pitched teeth (say, from ⅛ in. to 1 in. in broaches from 1½ ins. to 6 ins. diameter), and each cutting tooth increasing by 0·0005 in. The cutting teeth are preceded by a plain part (to act as a pilot) about 2 in. long and 0·002 in. below the diameter of the first cutting tooth and diameter of the hole. From 6 to 12 teeth at the end of the broach are parallel and about 0·002 in. larger than the finished hole, to allow for creep. This dimension will vary with the springiness of the member. The teeth should have a parallel land of 0·02 in. and a top-take of about 10°.

Design of Broach.

The broach may be secured to the cross-head of the machine by means of a screw or a flat key, or a buttress-thread and pad, a plain cylindrical stem with cotter. An example of the latter is shown in fig. 10. This method is extensively used, on account of the ease with which the pin can be withdrawn and the security it affords, in that the pin is sheared before any damage is done to the broach or machine.

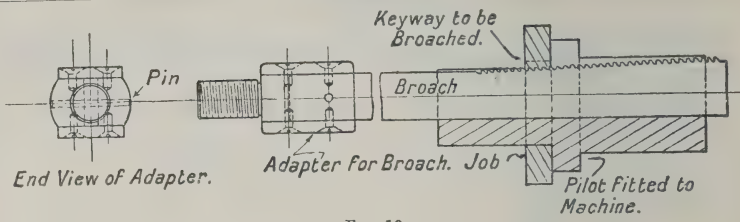

FIG. 10.

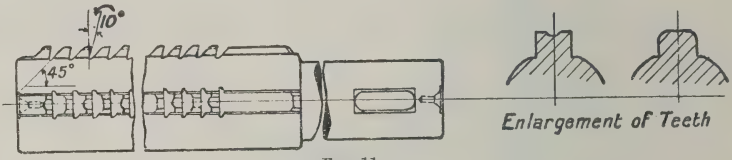

FIG. 11.

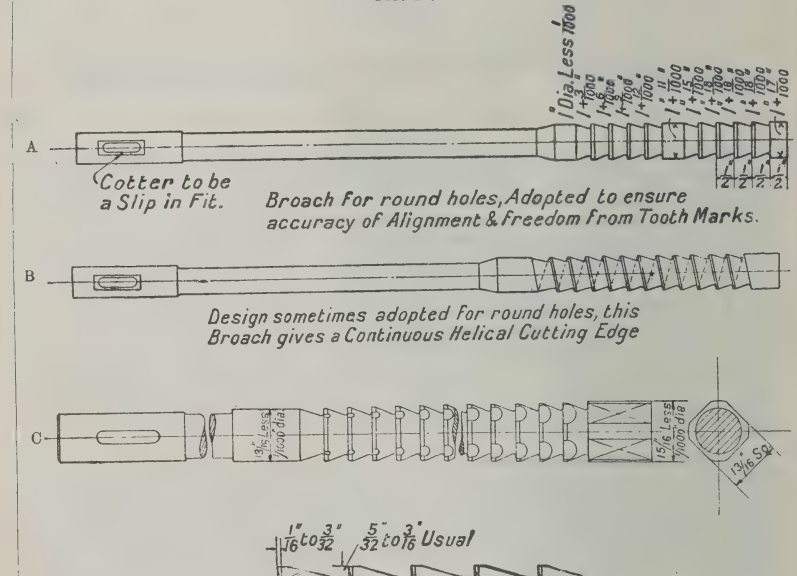

FIG. 12.—Types of Broaches.

All broaches should be provided with a pilot. The pilot is made a sliding fit in the hole or slot, and leads the cutting edges centrally to their work. It is a very important factor, as it not only helps to produce accurate work, but prevents damage to the broach. In the case of very long broaches, pilots or steadies are provided at intervals along the broach itself, as shown at A, fig. 12. It is advisable that the broach should have four or five teeth at the end for sizing only. These may be of a smaller pitch than the normal, as the cut removed per tooth is exceedingly fine. C, fig. 12, shows a square broach with progressive increasing cut per tooth which in this design is permissible.

Pitch of Teeth.

The pitch of the teeth is regulated by the number of teeth engaged, the cut taken per tooth, the material operated upon, and the material of which the broach is made. It is clear that the cutting force should not exceed the tensile strength of the broach or strength of the teeth. In the case of broaching, a circular, square or hexagonal hole in mild steel, it is usual to allow of three teeth being in action, each tooth taking $\frac{3}{1000}$ in. cut, that is, 9 teeth thousandths. This is suitable, say, for a broach 1 in. dia., but for a broach $\frac{1}{2}$ in. dia. only 5 teeth thousandths should be allowed, whilst for a 2 in. broach 18 teeth thousandths can be allowed, and a proportionately larger amount as the diameter of the broach increases. With softer material more teeth can, of course, be engaged. It is desirable that the teeth should have a top rake of about 10°, a land of about $\frac{1}{32}$ in., and a side clearance of about 3°, as shown in fig. 8. Proportions of teeth in common use are shown at D, fig. 12.

It is difficult to obtain uniformity of cutting per tooth on the first trial, and the broach may be pulled through a sample piece, the amount removed per tooth being noted, and the teeth honed down where necessary. On rectangular and circular work the teeth are sometimes spiral as shown at B in fig. 12. This design has the advantage of giving a side rake to the cutting edges, and it is claimed that it tends to neutralise any lateral thrust. Occasionally the teeth are staggered, and where the material to be cut is very hard the teeth may be fluted or nicked. An example of the latter is shown in fig. 11, where the alternate teeth are arranged to remove the corner and body of the groove. This arrangement breaks up the chip and materially reduces the stress on the broach.

In fig. 10 is shown the design of a broach adopted for cutting single keyway in a member, and the pilot which is fitted to the machine to guide the broach. Where more than one key is required, arrangements are made to turn the member round, but the spacing obtained under such conditions is rarely accurate, and a better method is to provide for a double spline broach as shown in fig. 11. It is always desirable, where there is more than one gutter, to have a broach with the necessary number of splines.

Speed of Cutting.

The speed of cutting varies with the material operated upon, and for soft brass may be as high as 20 ft. per minute, and for medium hard steel about 5 ft. per minute. The cutting speed is relatively of little importance, and it is generally advisable to adopt about half the above speeds.

Lubrication.

When a highly-polished finish is required on ductile materials it is desirable to use a cutting compound, and on such materials one pint of oil mixed with 4 ozs. of flowers of sulphur has given good results. The J. N. Lapointe Co. recommends the following mixture when broaching mild steel :—

Mineral lard oil, 3 gallons ; water, 50 gallons ; and soda ash, 2½ lbs. The whole of the lard oil and soda ash should be mixed with 10 gallons of water and the remaining proportion of water added before putting into use.

For heavy duty use castor oil.

DRILLS AND DRILLING.

Cutting Edges of Drills.

The cutting edges of drills are formed by grinding the end facets at an angle as shown by A, C, B, fig. 13, and this angle varies from 5° for drilling hard metal, such as steel, to 20° for

soft metal, such as brass or copper. The angle of one cutting edge to the other varies from 45° for steel to about 35° or 40° for soft metals.

Drills for work of ordinary hardness are tempered to an orange purple; but if the metal to be

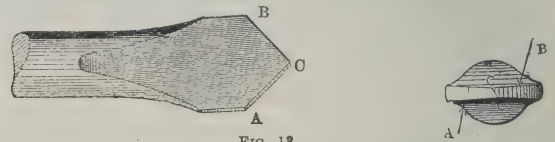

FIG. 13.

cut is very hard a straw colour is preferable, or the drill may be left as hard as it leaves the water; that is to say, hardened, but not tempered. In these cases great care must be exercised and the speed of the drill reduced.

Twist Drills.

A twist drill possesses three cutting edges, A, B, and C, as shown in fig. 14.

The point A, being the least effective, since it cannot be made anything like as keen as the other two, B and C, is a hindrance to clean and rapid cutting and is one of the most important factors to be considered when arriving at the amount of feed progression per inch of travel.

In order to obtain the greatest possible duty from a twist drill, it is imperative that it should be

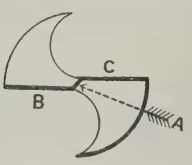

FIG. 14.

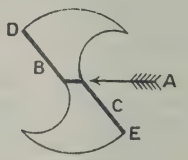

FIG. 15.

ground perfectly true, so that the point of the drill shall be central and in line with the axis on which it revolves. The cutting edges must be of equal length and at the same angle to the axis of the drill. If the point of the drill is not central to the axis, the two cutting edges are not at the same angle, the result being that all the duty falls on one cutting edge, and the hole made will still be larger in diameter than the drill, there being a tendency for the cutting edge B to push, or crowd, the drill over to the opposite side of the hole.

From the foregoing it will be obvious that the more correctly a drill is ground, the longer it will last without re-grinding; the greater its amount of feed may be to take an equal depth of cut, and the nearer the diameter of the hole bored will be to that of the drill.

Another important point when the maximum duty is expected from a twist drill is the relationship between the speed and feed, which varies more or less with different materials and with different grades of hardness of like materials.

When a drill has been in operation for a short time it should be withdrawn from the machine and examined as to its cutting edges, fig. 15. Should the cutting edges B C show more wear towards their extreme diameters D E, this would show the speed is too great as compared with the feed.

The grooves of a twist drill make either a constant angle with the axis or an angle that increases gradually from point to shank. The latter form is supposed to facilitate the escape of the cuttings, though opinions differ, but it has the serious effect of rendering the cutting angle more obtuse as the drill becomes ground back. When the angle is constant it ranges from 24° to 32° with the axis, measured at the periphery, 26° being an average. In the increase-twist drills it ranges roughly between 30° and 25°, the angle lessening by that amount from point to shank. The thickness of the web is increased from point to shank to enable it to resist torsional stresses. The diminished area for the escape of chips consequent on this thickening is counteracted by increasing the twist.

'FIRTH'S SPEEDICUT' HIGH-SPEED TWIST DRILLS.

(Thos. Firth & Sons, Ltd., Sheffield.)

The chart (fig. 16) indicates speeds and feeds suitable for drilling mild steel; for cast iron use the same feed per minute but decrease the speed 20 per cent. Both speeds and feeds may be modified to suit variation of material.

The feeds and speeds given on the chart are approximate, and represent ordinary working speeds for average depths of holes.

The chart shows that a 1-in. drill should run under the following conditions.

Mild Steel.	*Cast Iron.*
Speed, 280 revs. per min.	Speed, 224 revs. per min.
Feed, 4¾ ins. per min.	Feed, 4¾ ins. per min.
Feed per rev., ·0175.	Feed per rev., ·022.

If the material is thin, as in the case of boiler plate, both feed and speed can be increased. If the material is hard, decrease both the feed and speed. Always run with lubricant if possible except in the case of cast iron. If no lubricant is used, decrease both feed and speed about 25 per cent. When possible, always keep the feed per rev. the same as given on the chart for the

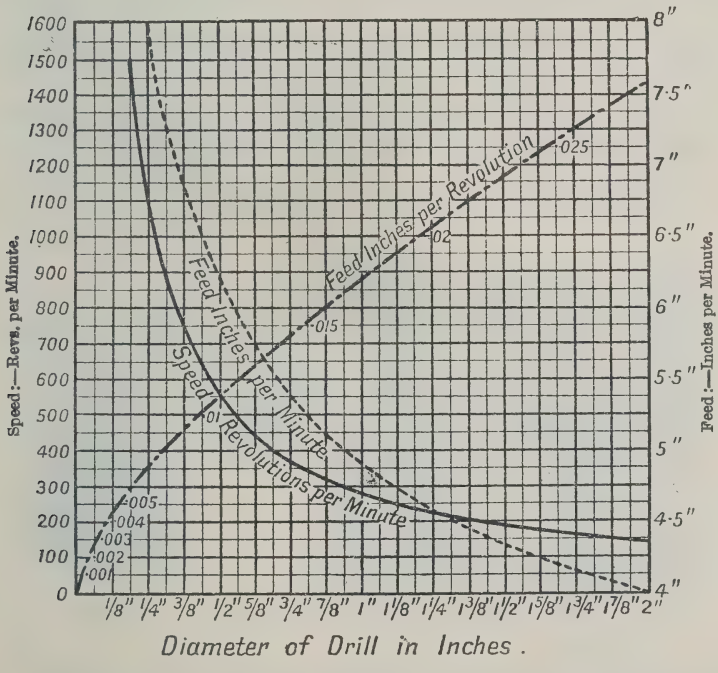

FIG. 16.

two different classes of material, i.e. steel and cast iron. Never decrease the feed below a minimum of, say, 3 ins. per min. for a 1-in. drill, the others in like proportion.

Feed revolutions for the above speeds, on wrought iron and steel: up to and including 1/4 in. diameter, 1/150 in.; from 1/4 in. up to 7/16 in. inclusive, 1/130 in.; from 7/16 in. up to 5/8 in. inclusive, 1/110 in.; from 5/8 in. up to 1 in. inclusive, 3/80 in.; from 1 in. up to 1 1/2 in. inclusive, 1/50 in.; from 1 1/2 in. upwards, 1/75 in. For cast iron these feeds may be increased 20 per cent.

For small holes in brass the feed should be from 0·0015 in. to 0·003 in. per revolution; 1/8 in. to 1/4 in. diameter, 0·003 in. to 0·006 in. per revolution; 1/4 in. to 1/2 in. diameter and upwards 0·006 in. to 0·020 in. per revolution. When drilling mild steel the feed should be approximately one-third the above, and harder metals slower in proportion.

Should the drill be running too fast the outer edge of the lip becomes quickly dulled; should the central stem become dull, or the lips chip, the feed is too great.

GRINDING DRILLS.

When grinding the drill points, the following rules should be observed:—

I. Both cutting lips, fig. 17, should be inclined at the same angle with the axis of the drill, and must be of equal length. The point angle of 59° has been universally adopted as best suited for average conditions.

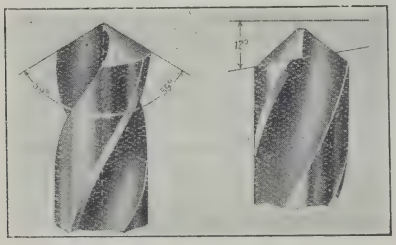

FIG. 17. FIG. 18.

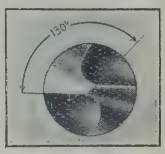

FIG. 19.

II. The drill point must have the proper clearance or contour of surface back of the cutting edges, and this clearance must be identical on both sides. Approximately a 12° clearance angle, fig. 18, combined with the centre angle of 130°, which will give a constantly increasing clearance toward the centre, fig. 19, has proved best for average conditions.

Some of the undesirable conditions resulting from drill points improperly ground are as follows:—

(1) If both lips are not ground at the same angle with the axis, fig. 20, one lip will fail to counteract the tendency of the other to spring away from the cut; consequently, one lip will do more work than the other, which will result in its becoming dull more rapidly than if both lips were cutting equally, and it will be subjected to an abnormal torsional strain.

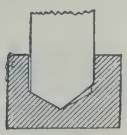

FIG. 20.

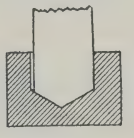

FIG. 21.

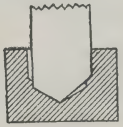

FIG. 22.

(2) When the cutting lips of a drill have the same point angle but are of different lengths, fig. 21, the point of the drill will be off centre, or eccentric. As a result, the hole will be oversize to an extent equal to double the amount of this eccentricity.

(3) If the drill point is ground both with lips at different angles and of different lengths, fig. 22, there will be a combination of the undesirable results described in the two preceding paragraphs.

(4) Fig. 23 shows a side and end view of a drill with the proper angle of point (59°) and the proper angle of clearance at the periphery (12°), but with insufficient clearance at the point or centre.

(5) Fig 24 shows a drill with insufficient clearance both at the periphery and at the centre. The line ABC is at an angle of 12°, but there is no clearance immediately back of the cutting edges (BC), and the excess of clearance at the heel (AB) is of no benefit.

(6) Fig. 25 shows what is liable to happen to a drill ground with insufficient clearance, or as described in paragraphs Nos. 1 to 5, especially if an attempt is made to obtain maximum production.

FIG. 24. FIG. 25. FIG. 26.

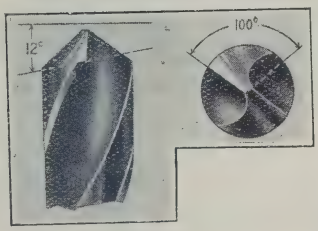

FIG. 23.

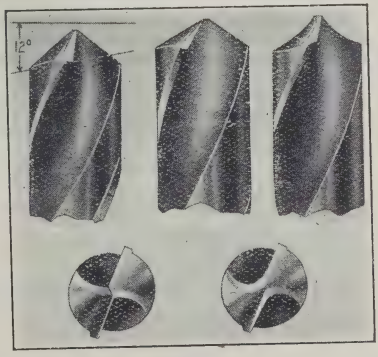

FIG. 27. FIG. 28.

(7) Fig. 26 shows a drill with a clearance angle of about 12°, but it does not have the proper contour back of the cutting edges. This manner of grinding leaves the cutting edges thin and weak, causing them to crumble away under heavy feeds.

Most twist drills are made with a gradual increase in the thickness of the web or centre of the drill toward the shank. As the drill becomes shorter and the web thicker, greater force

is required to drive it. To overcome this, it is good practice to thin the web by grinding away the excess thickness, reducing it to its original dimensions. This grinding must not extend too far up the flute of the drill, and care must be exercised that the cutting lips are not injured and the same amount is ground out of each groove. Fig. 27 shows a drill with the web properly thinned. In fig. 28 the grinding is excessive, leaving the web entirely too thin and liable to crumble. When this happens a split drill is practically inevitable.

Paragraphs 1 to 5 and the preceding paragraph show the cause of drills splitting up the centre, and no manufacturer should be called upon to replace a split drill unless a flaw is evident in the steel.

Twist drills are made with a slight taper from point to shank, so that the largest diameter is always across the corners of the cutting lips. This prevents the drills from binding in the work when they are sharp. If the outer corners are allowed to become badly worn, the drills will bind and cannot perform satisfactorily. Whenever the outer corners of the cutting lips show wear, the drills should be reground and every particle of worn surface removed, or the drill will continue to bind and very quickly be damaged beyond repair.

In grinding high-speed drills care should be taken not to overheat them, and when heated they should never be plunged into cold water. Doing so is likely to cause small surface cracks, which reduce the efficiency of the drill and may result in serious damage to it. Forcing the grinding on a wet grinder may also bring about the same condition.

It is hardly possible to do grinding as accurately by hand as by using a good twist-drill grinding machine.

Broken or damaged tangs of drills are generally the result of an imperfect fit of the drill shank in its socket, which may be caused by a worn-out socket, dirt or chips accumulating in the socket, or bruises on the shank of the drill.

In any case, the driving power of the taper is reduced or destroyed, resulting in an abnormal strain being put upon the tang.

A drill of either carbon or high-speed steel that can be filed is not necessarily too soft for service; in fact, if drills were tempered so that a good file would make no impression, they would be entirely too hard for general use. If there is any doubt regarding the temper, try the drills in actual service.

Assuming the drill is properly ground, when the corners of the cutting lips wear away rapidly it is an indication that the speed is too great. If the cutting edges roughen or break out in minute particles it indicates that the feed is too great.

It is seldom that very small drills can be run at more than a fraction of the speed necessary to obtain the best results, and excessive breakage is inevitable. They should be run true and the cutting edges kept sharp; a fine-grade emery stone is best suited for this latter purpose.

British Standard Specification for Twist and Straight Flute Drills.

(No. 328—1928.) (*Extract.*)*

Tables are given in this specification of the standard diameters, overall lengths, and flute lengths for the various types of drills, and the dimensions of the Morse taper shanks. Standard limits are laid down for the permissible variation in the diameter of the drills, and performance tests are specified for both carbon and high-speed drills from No. 60 to 2 ins. diameter, inclusive. The performance tests consist in drilling a series of holes, as continuously as possible, in steel billets of a given analysis. The penetration per minute and the number and depth of the holes to be drilled are specified, but the revolutions per minute and the feed per revolution are left to the discretion of the maker. The drills must withstand these tests without seizing, choking, or fusing, and the points of the drills and the lips must be in good condition and fit for further service without regrinding on completion of the tests. Standard nomenclature and definitions for the different types of drills in common use are also included.

Notes on Drilling.

The power for a given diameter of drill and feed is proportional to the cutting speed.

The horse-power is proportional to the torque, and for a given drill and speed does not increase as fast as the feed.

Since the torque is practically proportional to the diameter of the drill squared, the horse-power, for a given feed and cutting speed, is directly proportional to the diameter of the drill.

The horse-power per cubic inch of metal removed is inversely proportional to the feed and independent of the drill and cutting speed.

The work required to drill a given hole, when one drill is used, is greater than that required to drill the same hole in two operations with drills of different diameters. The greater the difference in the drill diameters, the greater the saving in work; speed and feed remaining the same throughout. This is due to the fact that the mean cutting angle of the single drill is greater than the average angle in use for the two drills and that the stress is proportional to the angle.

With twist drills of the usual proportions, the cutting angle is not sufficiently keen to drag the drill into the work when enlarging a hole in cast iron or steel.

The horse-power when operating on soft cast iron or medium steel varies as $t^{0\cdot7}$ (t = feed per rev.) for a given drill and speed.

The horse-power for a given feed and speed does not increase as fast as the diameter but varies as $d^{1\cdot8}$.

The torque and horse-power when drilling medium steel is about 2·1 times that required to drill soft cast iron with the same drill speed and feed.

The end thrust when operating on cast iron or steel does not increase in proportion to the feed for a given diameter of drill or in proportion to the diameter for a given feed.

While the chisel point scarcely affects the torque it is accountable for about 20 per cent. of the end thrust.

Lubricated trials on steel when compared with the dry tests show a diminution in the torque and horse-power, varying from 28 per cent. with the $\frac{1}{40}$ feed to 8 per cent. with the $\frac{1}{5}$ feed.

* By permission of the British Engineering Standards Association.

This may be due to the lubricant washing away the small metal chips which tend to jam between the walls of the hole and the drill, and to the preserved cutting edge. The diminished frictional resistance of the shaving across the lip together with above reduces the end thrust by about 25 per cent. for all feeds.

As the result of a series of experiments on twist drills, recently undertaken at the engineering experiment station of the Illinois University, the following lubricants are recommended:—For tool steel—lard oil, machine oil, turpentine, soda-water, kerosene; for soft steel—lard oil, machine oil, soda-water; for cast iron—dry or compressed air; for brass—dry or paraffin oil; for aluminium—kerosene, soda-water, and aqualine and soda-water.

The drill most commonly adopted in practice has an included angle, at the point, of 120°. If this angle is increased, the torque diminishes but the end thrust increases, while if this angle is decreased, the reverse is the result. So far as economy in power is concerned the torque is the factor to consider, as the feeding horse-power is only about 1 per cent. of the whole, in small drills, and very much less for the larger sizes. From this point of view the drill with the larger point angle is to be preferred. The accompanying increased end thrust, however, strains the machine parts in proportion. When the point of the drill breaks through the metal at the bottom of the hole, a considerable portion of the end load is removed. The strain due to that load is released, thereby causing the drill to advance more than its rated feed, and possibly to break. The drill with the greater included angle will be most likely to give trouble in this direction, both on account of the increased strain and torque, and conversely.

By decreasing the spiral of the drill a keener cutting angle with a decreased end thrust and torque can be obtained without altering the point angle above the accepted standard, 120°. This, however, would in turn affect the durability of the drill.

With a small included point angle there is little metal to support the cutting edge at the chisel point, and trouble due to blunting of this part is to be expected.

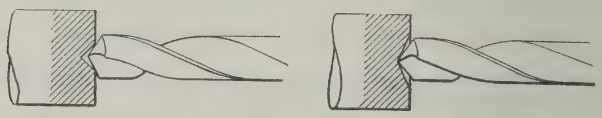
The endurance of a drill may be increased by from 300 per cent. to 1,000 per cent. by rounding the sharp corners at the periphery.

In estimating the time required to drill a hole of given depth, the length of the drill point must be taken into account. The length of the point for different included point angles is:

$$90° = 0{\cdot}5d\,; \quad 120° = 0{\cdot}29d\,; \quad 150° = 0{\cdot}134d.$$

In the course of a paper read before the Institution of Production Engineers, Mr. L. C. Keen gave the following advice:—Do not attempt, on drills below $\frac{3}{16}$-in. diameter, to drill a depth more than three times the diameter of the drill, without drawing out to clear the chips; if the drill as well as the work is revolved, however, it can be easily fed in to a depth of five times the diameter, at one traverse.

True drilling is usually dependent upon good centering, and it may be advisable to draw attention to the well-known but often ignored rule, namely, that the centering tool must have a lesser cutting angle than the drill point, otherwise the drill will strike on the point, wobble, start out of centre, and sometimes break.



A *B*

FIG. 30.

Good centering. Bad centering.

Fig. 30 shows good centering at *A* and bad at *B*. As a general rule the centering drill should ave an included angle of 100° against the standard angle for the drill point of 119°.

(*Machinery.*)

See also '*Smith & Poliakoff: Proc. Inst. of Mech. Engrs.* 1909.')

A high efficiency can be obtained by fitting all running bearings of drilling machines (including the spindle bearings) with annular ball bearings, which never require adjustment. The fact that the spindles themselves have no sleeve or rubbing bearing whatever enables even the smallest sizes of high-speed drills to be run at their proper speeds. At the same time the saving in friction all over the machine permits the feed to be quicker, and enables larger holes to be drilled than has been hitherto possible with ordinary sensitive machines.

Vulcanised fibre is being applied to the thrust bearings of light, sensitive, drilling machines. Ball bearings cause considerable trouble if one of the balls fractures or chips, and it has been found that a fibre disc answers the purpose admirably. The permeability of the fibre to oil renders it self-lubricating, and its life under these conditions is remarkable. (*Machinery.*)

Small Drill Protector.

The function of this protector is to stiffen the shank of the drill, leaving exposed a length o the drill sufficient only for the depth of the hole to be drilled. The protector, fig. 31, consists of a length of hard brass, drilled from one end to the other, and with about three-quarters of its length slotted on one side, the internal diameter being equal to the diameter of the drill to which it is to be applied. To use the protector, the drill is inserted therein with the cutting point projecting from the chamfered end, the exposed length being equal to the required depth of the hole to be drilled. The split end of the protector is inserted into the drill chuck so that it is

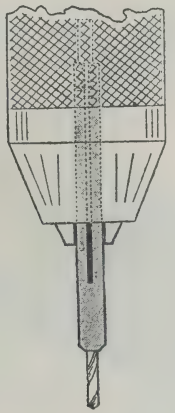


Fig. 31.

secured for about half an inch of its length, the chuck then being tightened up in the usual manner. If it is required to drill a hole of greater depth than usual all that is necessary is to release the chuck and slide the protector farther up the drill for the extra length required and then tighten up the chuck again.

The protectors are supplied suitable for short or long length drills in sizes varying from $\frac{1}{32}$ up to $\frac{1}{4}$ in., from 20 to 66 wire gauge sizes and from 1 to 2 mm.

Lubricant for Drilling and Tapping Copper.

Milk, 50 parts; Water, 45 parts; Turpentine, 2·5 parts; Paraffin, 2·5 parts.

Portable Electric Drills.

The Van Dorn Drill.

These tools, fig. 32, are made by the Van Dorn & Dutton Co., Cleveland, Ohio. They are designed so as to be easy to handle, and are light and compact. The machines designed to take drills up to ⅝-in. diameter may be operated by either direct or alternating current. Another advantage of the design lies in the fact that the drill spindle is offset, so that holes may be drilled close to a flange or similar projection.

The Gear Case is a light aluminium casting reinforced with ribs to resist distortion. This case is not only an efficient housing for the gears, but forms a grease chamber from which the gears and main spindle bearing receive ample lubrication. Each end of armature shaft runs in a ball journal bearing fitted in a steel housing, and the thrust is also taken on a ball thrust washer. The gear spindles run in high-grade phosphor bearings.

The Gears, accurately generated, are made of special heat-treated steel, hardened and ground.

The Motor is series wound. The adoption of this type of winding renders the speed automatic, the pressure used to force the drill into the work governing the speed of the drill. The armature and field coils are form wound and thoroughly insulated.

The Armature is of the slotted drum type built up of soft steel laminations, these being made from special steel adapted to the purpose and uniformly insulated. On the DC.2 and larger machines the armature is built on a hollow shaft to preserve lightness.

Ventilation.—One of the distinctive features of the Van Dorn drills is the system adopted for thoroughly cooling the motor. It consists of a large aluminium fan of special design, screwed on the armature shaft. It is so constructed and placed in such a position as to draw out the hot air at one end of the machine, to be replaced by cool from the other. A constant draught is therefore maintained, ensuring a low temperature.

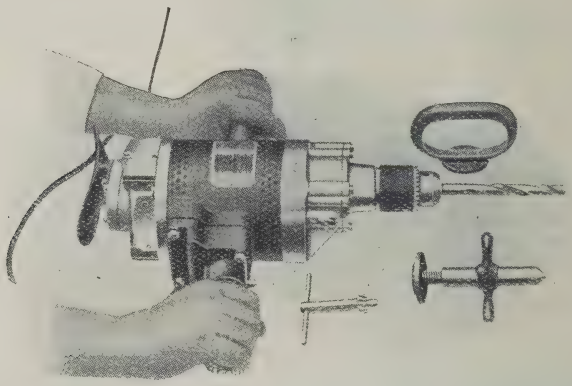

Fig. 32.

The Switch is of the quick-break type with a capacity of 5 per cent. above the duty required. By the use of release attachments the switch has the same rapidity in breaking as in the making contact. The larger sizes are provided with a quick-acting self-releasing attachment.

A Safety Fuse, consisting of a small piece of fuse wire held by screwed terminals, is fitted to machines up to and including ½-in. capacity, and may be quickly replaced if necessary; this prevents the possibility of damage to the machine from overloading or from a short circuit, which is generally caused by the operator omitting to clean the commutator.

STANDARD WORKS

Surveying as Practised by Civil Engineers and Surveyors

Including the Setting-out of Works for Construction and Surveys Abroad, with many Examples taken from Actual Practice. A Handbook for Use in the Field and the Office, intended also as a Text-book for Students. By JOHN WHITELAW, A.M.Inst.C.E. Eighth Edition, thoroughly Revised and Enlarged, by Colonel Sir GORDON R. HEARN, C.I.E., D.S.O., Assoc.Inst.C.E., and late Chief Engineer, Indian State Railways. 594 pages. 297 Illustrations. Demy 8vo, cloth *Net* **16s.**

THE LITTLE GIANT ELECTRIC DRILL.

(*The Consolidated Pneumatic Tool Co., Ltd.*)

This drill, fig. 33, is made in many sizes and in A.C., D.C., and universal types. The armature is built up on a one-piece shaft and pinion, hardened and ground, ensuring perfect alignment of pinion at all times. On large sizes, the armature core and commutator are mounted on sleeves, and may be removed from the shaft. Forced ventilation is obtained by means of a fan mounted on the armature shaft. The coils of the armature are former wound, heavily insulated, and carried in insulated slots in the armature core. Other important features are: The use of ball

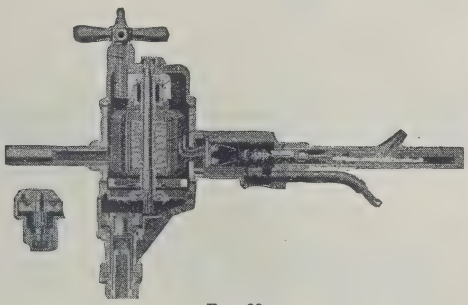

FIG. 33.

bearings, long feed screw (entering into the body of supporting bracket), thus giving the same rigidity as a telescopic feed; also a quick-acting control switch, making slow break impossible and preventing destructive burning of contacts, and a removable, and therefore easily replaced, tool socket in the spindle.

THE LITTLE GIANT ELECTRIC HAMMER DRILL.

(Universal Type.)

(*Consolidated Pneumatic Tool Co. Ltd.*)

This tool (fig. 34) is equipped with a universal motor, and will operate on direct or alternating current. It is designed for drilling in stone or concrete where a hammer blow is necessary to do effective work.

The blow is delivered on the head of the drill bit by a piston governed by compressed air, consequently the electric motor is not subjected to serious mechanical strains or vibration. The tool is well balanced and all parts readily accessible. A switch is conveniently located in the

* Extensive tests have shown this to be a reliable basis for determining power requirements.

handle for the control of the electric current. All bearings throughout are of the latest ball type provision being made for the easy lubrication of all revolving and reciprocating parts.

Wound for 110 or 220 volts (Universal Type, to operate on either D.C. or single-phase A.C.).

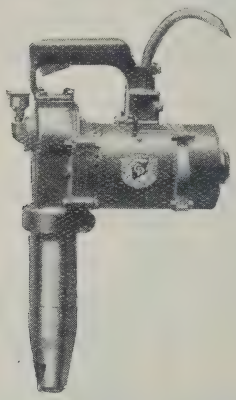

FIG. 34.

Size	No. 1	Weight . .	24½ lbs.
Maximum capacity, in stone or concrete	1 in.	Overall length	17½ in.

Equipment.—Three yards of flexible cable. Two drill steels. Specify type, diameter, and length when ordering. If the tool is required for light chipping, two flat chisels will be supplied instead of drill steels.

Energy consumption . . . 310 watts.

THE LITTLE GIANT AIR DRILL.

(The Consolidated Pneumatic Tool Co., Ltd.)

Fig. 35 shows a Little Giant Air Drill in section. This particular machine, which is representative of the majority of air drills on the market, has four cylinders arranged in pairs diagonal to a two-throw crankshaft, thus two cylinders diagonally opposed operate on one crank,

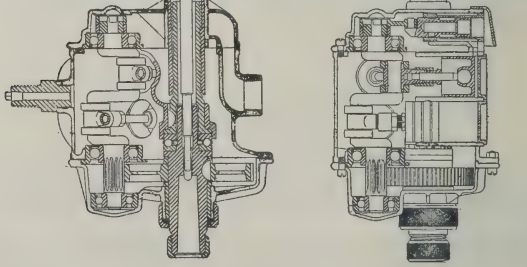

FIG. 35.

given the maximum power for the minimum weight and overall dimensions; such an arrange ment also gives best mechanical balance and freedom from vibration.

One end of the case carries a feed screw, breast plate or grip handle, the other the drill chuck. On each side (usually carried from stout bosses on the drill case) are two handles, usually of steel pipe for lightness, one handle acting as air inlet and having a cock or throttle incorporated therein. See fig. 36.

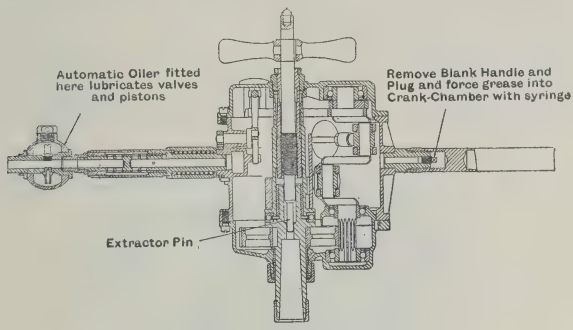

FIG. 36.

Bearings are usually of the ball or roller type, as these suit the high speeds and powers which are developed in such relatively small frames. Sometimes even the big ends of the connecting rods are fitted with balls or rollers, though this is exceptional.

As these machines develop very considerable power (from 1 to 5 h.p.) for their size and weight, it is necessary to use high-grade materials, consequently special steels are used, and all parts are specially heat treated and ground to a finish.

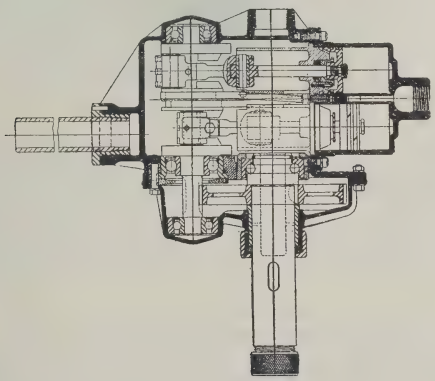

FIG. 37.

Generally, piston or corliss type valves are used, operated by eccentrics of the usual type. Occasionally, a flat plate type of valve is employed, and sometimes a rotary valve has been used with success, the latter being driven by a spur wheel from the main shaft.

A type of tool made by the Consolidated Pneumatic Tool Company is the 'Red Giant,' fig. 37, which contains a twin cylinder double-acting engine. This engine develops equal power to a four-cylinder type, and has crosshead guides, piston valves, and a two-throw balanced crankshaft.

One problem with these small high-speed air engines is the lubrication of the parts, as the drill has to operate in any position that the user may find convenient. Sometimes it operates with the crankshaft horizontal, sometimes vertical, and often at any intermediate position which is necessary on the job, and the difficulties are still further complicated by the necessity of providing the crank case with a 'breather.'

Fig. 38 shows the arrangement introduced by the Consolidated Pneumatic Tool Company. By this arrangement the atmosphere is admitted automatically at the top end of the crank case only, *i.e.* at the end where there is no oil. A tube, which is open to the atmosphere through a **T**-piece in the middle and may be closed at either end by a double cone-shaped plug, which is free to move inside the tube, is fitted approximately parallel to the crankshaft. When the

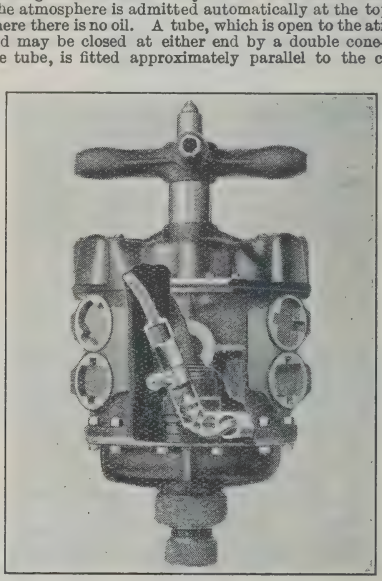

FIG. 38.

machine stands with the drill point downwards, the oil is obviously at the lower end of the crank case, and the lower end of this tube is submerged in oil. The cone plug also falls to this end and closes the tube, so that no oil can be blown into it, and at the same time leaves the top end free to breathe to the atmosphere through the **T**-connection, to the outer air.

If the tool is turned upside down, the oil flows to the other end of the crank case; the cone plug drops to the other end also and now closes that end.

If the machine is operated with the crankshaft horizontal, the cone plug takes no definite position, and the crank case may breathe through either end, and no oil gets blown out.

Drilling Appliances.

THE 'SELSON' GRAVITY DRILLING MACHINE VICE.

In this arrangement, fig. 39, the jaws are opened by sliding them up the angle guides, the maximum opening of the upper jaws being 8 ins., the lower 2½ ins. When the work is set, gravity, supplemented by the pressure of the drill, forces the jaws downwards in the guides, ensuring an absolutely firm hold of the work and making the vice practically an automatic tool.

A slight turn of the handle prevents the work from becoming slack when the pressure on the drill is decreased at the bottom of the hole.

The vice can be used loose on the machine table, except in extreme cases. Slots are, however, provided for bolting it down.

The vice will securely hold all round work from ½ in. to 8 ins. diameter. Work is ensured against turning, even with slight pressure on the drill. Special shapes are held as firmly as regular ones.

There are but five main parts in the vice, which adds to its simplicity.

Size of base, 12 ins. × 6½ ins. Approximate weight, 45 lbs.

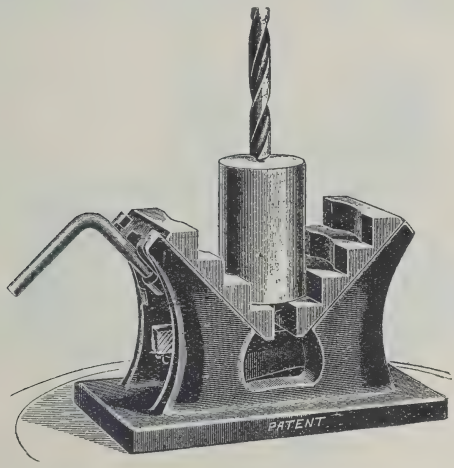

FIG. 39.

V-BLOCK WITH ADJUSTABLE CLAMP.

A compact method of fitting a clamp to grip work in a V-block for marking or for drilling purposes, is to make the block with uprights composed of two plates attached to the ends of the block (fig. 40). Three pinholes are drilled through the uprights, into which an ordinary headed pin is slid to sustain the cranked clamp seen. This is tightened down upon the work by setting up the screw. (*'Machinery.'*)

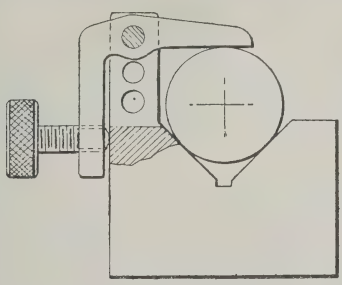

FIG. 40.

THE 'BROOKE' QUICK-CHANGE UNIVERSAL DRILL JIG.

This arrangement (fig. 41) is for the purpose of drilling pin holes in bolts, studs, pins, etc., for split pins, etc. It consists of a baseplate, on which are mounted two pillars carrying, at the top, a steel cross beam, which serves as a clamp for holding the work and also as a guide to the drill by means of suitable bushes. The jig can either be used on a table with a plain surface or bolted down, as required. For plain service tables, a locating pin is supplied to fit the base-

plate and hole in the centre of drilling machine table, keeping the guide bush in the cross beam always in line with the drill spindle.

The work is held in a V-block, provided with a groove on each side, fitting the square portions of the pillars, which thus act as guides, enabling the block to be rapidly adjusted to the required position indicated by pointer and rule, and afterwards locked in place by a small lever instead of the hexagon nut shown in the fig. This block admits bolts from 1½ in. to ¾ in. diameter,

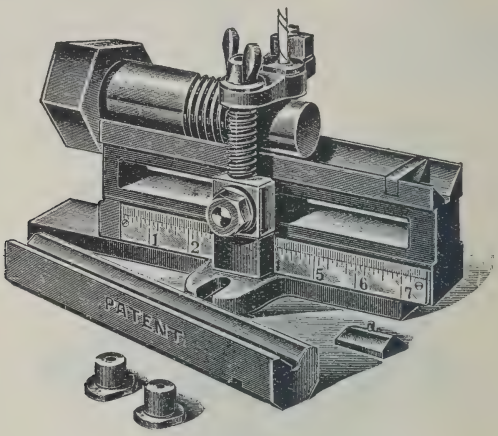

FIG. 41.

and for smaller work an additional V-block is supplied, which fits into the larger one, and can be used for objects down to ½ in. diameter. For studs and other parallel work, steps are provided on the right of both V-blocks, against which the end of the stud rests.

MAGNETIC CHUCKS.

The Magnetic Chuck is now largely used for holding machine parts of iron and steel for grinding, turning, and planing operations. Many pieces, such as milling cutters, thin saws, air-compressor valve discs, chain links, etc., can be more effectively held by this method than by any other. Not only is there a great saving in the time ordinarily required for setting up, but the likelihood of distorting the job due to unequal straining of the holding down bolts is eliminated.

It must be understood that the holding power of a magnetic chuck depends as much on the shape and section of the piece to be held as on the magnetic chuck itself. If the piece is small in section the hold will be very light, no matter what the section or intensity of the chuck magnets may be. The hold is entirely dependent upon the number of magnetic lines that can be passed through the section of the piece, and not on the total magnetism that the chuck can produce. Some makers claim a holding power of 100 lbs. per sq. in., this having been attained on a perfectly surfaced cube of Swedish iron applied between the chuck poles. This affords no useful measure of the holding value of a magnetic chuck, as theoretically a small magnet either of steel, wrought iron or even cast iron, if perfect at the joints, would give (on such a cube) 100 lbs. per in. On the other hand, if two such cubes were placed together the pull would not be proportionately increased, as the magnet being small the section of the first cube would absorb all the magnetism it could supply. Thus a chuck, say 30 ins. by 8 ins., which would pull 100 lbs. on any sq. in. of its surface could not, under any circumstances, pull 30 ins. by 8 ins. by 100 lbs., or nearly 11 tons, on its entire surface. The pitch of the poles should be arranged to suit the class of work to be held; if the pieces are of heavy section, the magnet must be of heavy section to get the best results.

Fine Grinding.—For fine grinding it is well to reduce the magnetic pull of a chuck face, either by inserting resistances in the coil circuit, or by the interposition of non-magnetic material

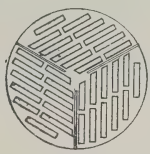

FIG. 42.

between the work and the chuck face. The lighter the pull the more accurate the resultant work. Specially constructed chucks of a very light but even pull are necessary for thin saws, light piston rings, etc. Grinding with water, soda and other liquids makes it absolutely essential that the magnetic chucking apparatus must be impervious to water. In the Humphreys chucks

FIG. 43.

FIG. 44.

FIG. 45.

FIG. 46.

FIG. 47.

one of the leading features is the insulating method employed. The wire itself, before winding, is insulated with a special liquid having very high insulating properties and capable of withstanding weak acids, alkalies, saline solutions, or alcohol. After winding and coating with a special fabric for mechanical protection, the coils are heated to 200° F., and placed in a heated

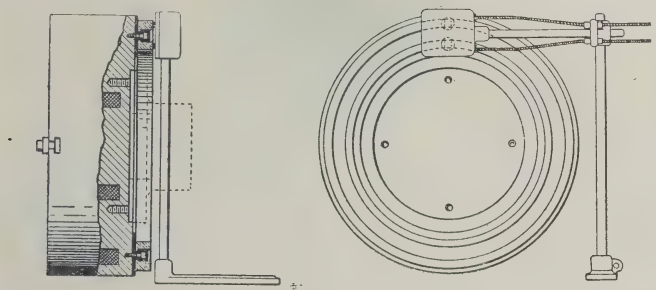

FIG. 48.

tank from which all air and moisture is then extracted. After being subjected to this high vacuum for some time, the tank, without breaking the seal, is filled with a liquid asphaltum compound at high pressure, rendering the coils absolutely proof against moisture, etc. The coils are then placed in position over the cores of the magnets, and the whole chuck body filled and made solid with the asphaltum compound.

Fig. 42 shows the face of a Humphreys (Pat.) circular chuck suitable for piston rings, saws, milling cutters, and general work. These chucks are constructed in sizes ranging from 6½ ins. diameter to 72 ins. diameter. Other designs of chuck faces for special work are shown in figs. 43,

44, 45, 46, and 47; the finer pole designs being used for very small pieces, and the simpler 8-pole design for larger section pieces.

The method of current supply is shown in fig. 48; this is used for dry grinding only. The chuck is fitted to a lathe or grinding machine spindle exactly as an ordinary mechanical chuck.

The brass slip-ring running with the chuck itself collects the current from a contact box, which is held by a tubular support from the lathe or machine bed. The contact box contains a pair of carbon brushes actuated by springs; these brushes are totally enclosed. The method is simple and effective, especially in cases where the chuck is only used occasionally and the apparatus has to be removed and set up each time. Fig. 49 shows an arrangement adopted by the above makers for both horizontal and vertical machine spindles. A hollow spindle machine

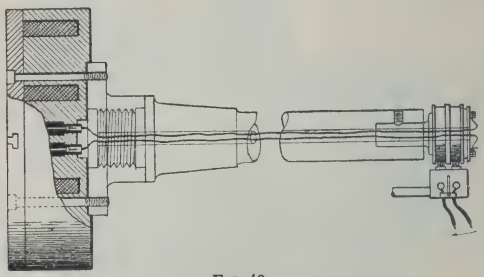

FIG. 49.

is necessary in this case, and the advantage is that all water suds or soda mixture is kept entirely away from the running contacts. The current is carried from the contact rings through the spindle, and is conveyed to the chuck windings by means of a pair of plugs fitting directly into the back of the chuck.

Magnetic chucks are not adaptable to alternating current, and must be used on the voltage for which they are designed. If a higher voltage be applied there is a likelihood of burning out the coils, and with a lower voltage the full power of the chuck is not developed. Fig. 50 shows

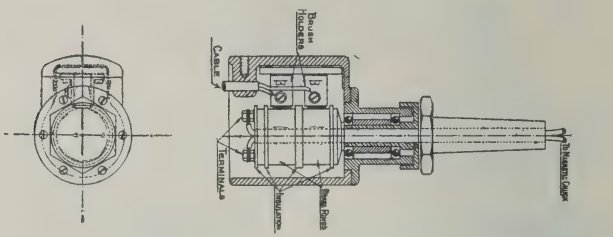

FIG. 50.

the contact arrangement when used with a vertical spindle; it is totally enclosed, the shank is tapered and fitted with a nut to facilitate removal. An oil throw or guard is provided to keep off the bearing oil.

Flat Chucks.—In fig. 51 is shown the details of the 'Humphreys' standard flat chucks, suitable for grinding, planing, and milling machines. These are constructed in sizes up to 72 ins. by 10 ins.; they are fitted complete with a rise and fall parallel strip and an adjustable end-stop. Movable fingers or clamps may be set to support work set on edge; these fingers are secured by set screws in a T-slotted bar, which may be fixed conveniently at any height. The end-stop is necessary to take the thrust of a milling or planing cut; in most grinding operations it is not necessary to use it.

Fig. 52 shows a variation of this form of chuck for machining taper pieces. This chuck is carried on a sub-base hinged at one end, and has a fine knurled screw adjustment at the other. The index graduation is in inches per foot. When the setting is at zero the chuck can be used for ordinary flat work.

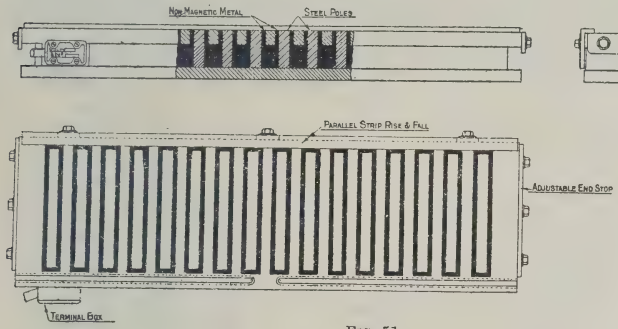

Fig. 51.

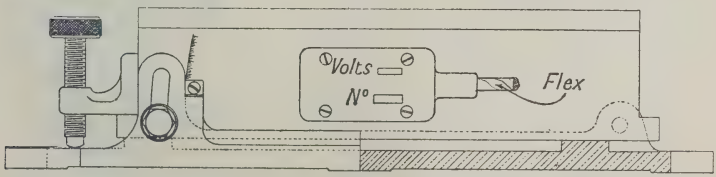

Fig. 52.

To facilitate the grinding of square sections on the chucks shown in figs. 51 and 52, an attachment has been recently devised. This consists of a rectangular block made up of steel plates of very high magnetic permeability interspaced with non-magnetic material. Placed on the chuck face without any connections, either mechanical or electrical, it brings into operation a vertical magnetic face by means of which work can be set up and ground square.

To grind a rectangular piece, grind two opposite faces on the magnetic chuck in the ordinary manner, then by holding the piece by one of the ground surfaces against the side of the attachment and supported underneath to the requisite height, a perfect square can be obtained.

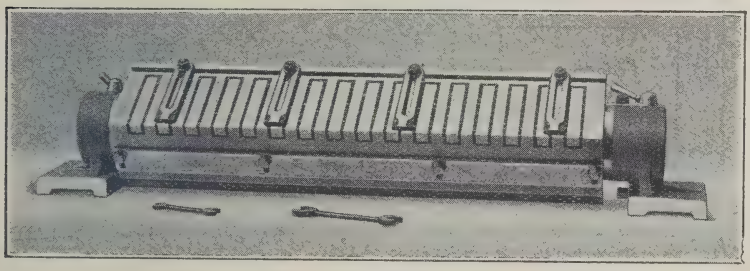

Fig. 53.

A new Humphrey Swivelling Chuck is shown in fig. 53. A graduated ring enables the operator to set the chuck at any desired angle.

The poles on this chuck are carried right up to the edge, thus permitting narrow pieces to be held on the side as well as on the top face of the chuck

Switches.—One of the most important pieces of apparatus in connection with the magnetic chucks are the switches used for operating. When the current from a magnetic chuck is cut off, a back current is induced in the chuck coils. This induced current is of a very high voltage, and if the switch gear is not perfectly designed to deal with it, the insulation of the chuck, however well designed and carried out, will inevitably break down. The switch must be double-pole, that is, it must operate on both the positive and negative supply wires at the same time, also it must be capable of admitting current to the chuck in either direction, and in order to deal with the induced back current when switching the chuck off, it must be provided with a non-inductive resistance which must automatically be put in circuit with the chuck prior to breaking the circuit. Fig. 54 shows the 'Humphreys' No. 7 Demagnetising Switch. To operate it the

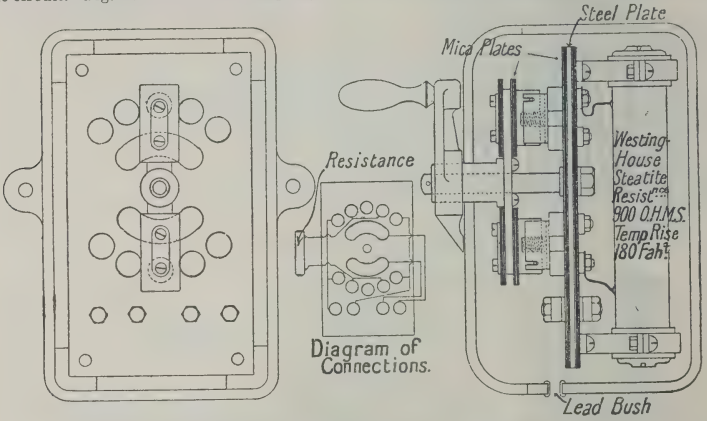

FIG. 54.—No. 7 Demagnetising Switch, Slow Break, Capacity 2 Amps.

switch handle must be moved past the 'Off' position and held momentarily on the 'Reverse,' going back quickly to the 'Off' position; this is for the purpose of demagnetising the chuck sufficiently to allow of the work to be easily removed. The view on the left of the figure shows the arrangement of contacts. For very large chucks a special oil-break switch is furnished; the method of operation is similar to that of the No. 7 switch, but the contacts are immersed in oil and the non-inductive resistances are carried in a separate iron case forming the base of the switch.

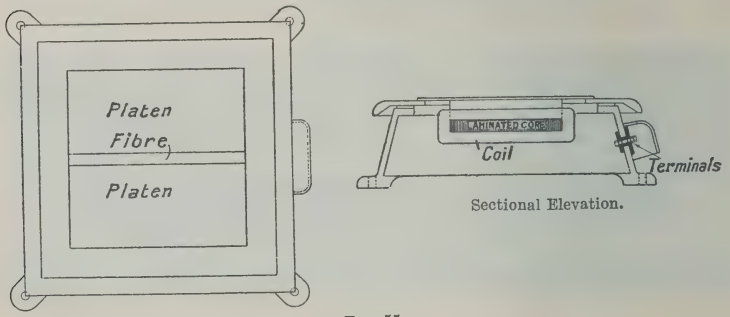

FIG. 55.

The sectional view on the right-hand side of the figure shows the non-inductive resistance. The main plate is mica insulated; in several sizes of switches this main plate consists of a slab of slate.

The arrangement of the connections, etc., is shown in the central view of fig. 54.

Demagnetisers.—Consequent on the use of magnetic chucks is the permanent magnetic condition imparted to the finished work, which with milling cutters and similar articles would prove a decided objection. A magnetised milling cutter would collect to itself the cuttings as produced, and though this might not impair its efficiency as a cutter, it would be a source of annoyance to the operator. Fig. 55 shows a sectional elevation and plan of a demagnetiser by J. H. Humphreys & Sons. There are two working platens, and all that is necessary is to pass the work over these platens, when it will be instantly demagnetised. As shown in the section drawing, immediately under the working platens is a powerful laminated magnet, which takes from the transformer a low period, low voltage, alternating current. The transformer carries

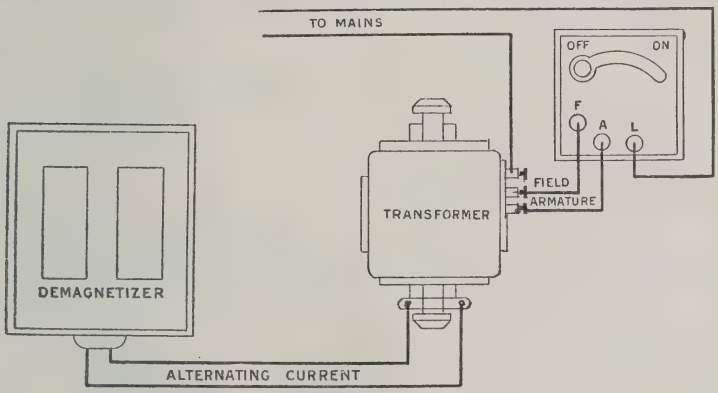

FIG. 56.

a double winding, one connected to a pair of slip-rings at one end of the shaft, the other being an ordinary motor winding which is connected to the mains through a starting rheostat exactly as an ordinary electric motor. This arrangement is very convenient, no fixing is required, and the demagnetiser can be placed in any position independent of the transformer.

The whole apparatus, fig. 56, includes demagnetiser, rotary transformer, and starting rheostat.

Felt Wipers on Slides.

To prevent grit working under the slides of machine tools owing to rounded corners, felt wipers may be fitted as shown in fig. 57. The felt is held in place by 1-in. angle iron secured to

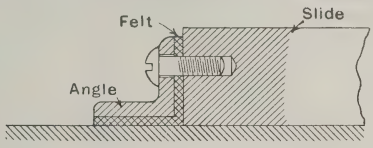

FIG. 57.

the slide by button-head screws. In practice the felt retains the oil and helps to keep the slide lubricated. (*Machinery.*)

MILLING SPEEDS AND FEEDS.

With regard to milling speeds and feeds, the amount of reliable experimental data available is very meagre and the machinist must for the present content himself with compiling data for himself. The subject is very complicated, and he will require to make the fullest possible observations at least at the commencement. For this purpose, he will note the following: dia. and width of cutter, revs. per min., depth and width of cut, feed in inches per min., number of teeth in the cutter, type of cutter, feed per tooth, material and nature of the work. To measure the capacity of the machine by the feed per tooth alone may give misleading results.

TESTS MADE ON A NO. 22 'SINGLE PULLEY' HORIZONTAL MILLING MACHINE MADE BY MESSRS. ALFRED HERBERT LTD., COVENTRY.*

WOOD-WORKING MACHINERY.

The following allows for the motors being capable of giving 25 per cent. overload for not less than $1\frac{1}{2}$ hour, without any undue heating. The figures are based upon the average work found in the particular shops where the machines are generally used. The type of motor chosen has a certain influence upon the amount of marginal power, and this point requires careful attention.

MACHINE TYPE AND SIZE.	POWER OF MOTOR REQUIRED FOR AVERAGE WORK. H.P.	MOTOR BELTED TO THE MACHINE OR COUNTER, OR DIRECT COUPLED.	REMARKS.

24 in. Combined Surfacing and Thicknessing Machine	10	" "	

When motors are direct coupled it is advisable to use a flexible coupling in order to avoid shock on the motor due to fluctuating loads.

The foregoing powers assume that the cutters or saws are running at about standard speeds, and are in good working condition; also it is assumed that the rate of feeding is about the standard, and not speeded up above the makers' speeds. It is, of course, understood that any machine, particularly saw benches, can be fed until they take an abnormal amount of power, but the intelligent workman can so humour the feed without losing time that he gets almost the maximum amount of cutting done with the minimum amount of power expended.

The power absorbed per sq. ft. surface sawn per minute varies very much in some instances and it is impossible to get anything like an accurate figure, as there are so many variable factors; thus, the amount of power absorbed by the saw increases or decreases according to the amount

of set given to the teeth, and the set requires to be varied considerably according to the class of timber to be sawn: even in the same class of timber the grain in one part of the cut might be such that it closes in on the saw more than in another part of the cut.

SPEED.

The speed of the cutting edge and the angle, in knife tools, and the shape of saw tooth, speed, angle, and thickness of saw, in saws, has a great influence on the amount of power a machine will absorb when doing certain classes of work.

The following list gives the various speeds, etc., of certain machines, the information being the latest practice.

Circular Saws for ripping, soft wood	9,600 to 11,000 ft. per min. (peripheral)	
" " hard "	9,600 to 11,000 " "	
" " ordinary cross-cutting, soft	10,000 " "	
" " " " hard	8,000 to 10,000 " "	
" " (Hollow ground)	10,000 to 11,000 " "	
Ordinary plain Band Saws, soft wood	4,300 to 5,000 " "	
" " hard wood	4,300 to 5,000 " "	
Deal cutting Band Saws, hard or soft	6,500 to 7,000 "	Specially designed
Log Band Saws	6,500 to 8,000 "	machines

Reciprocating Mortising Machines:

Mortising up to $\frac{7}{8}$ in. wide,		$4\frac{1}{2}$	ins.	stroke	(not graduated),	crankshaft speed	400	r.p.m.

" "	48	"		"	"	"	"	230	"

Double Equilibrium Deal Sawing Frames (balance swing frames):

To cut 2 deals up to 14 inches × 5 inches, 350 revs. per min. (of crankshaft).

"	"	18	"	× 6	"	300	"	"	"
"	"	24	"	× 7	"	250	"	"	"

Bandsaws, blades running on wheels up to 3 feet diameter:

For sawing very hard ivory, etc., traverse of saw blade per minute, 750 feet.

" iron " " " " " " 250 "

Vertical Spindle Moulding Machines:

Single Spindle (light type)	5,000 to 6,000 revs. per minute.	
Double " (")	5,000 to 6,000	" "
Single " (medium type)	4,000 to 4,500	" "
Double " (")	4,000 to 4,500	" "
" " (heavy type)	3,500 to 4,000	" "

High speed Four Cutter Moulders:

Bottom spindle	4,000 revs. per minute,	6 ins. dia. cutting circle app.			
(2) Side spindles	4,000 "	"	6 "	"	"
Top spindle	5,000 "	"	6 "	"	"

The above represents the average machine up to 12 ins. by 4 ins., and gives approximate peripheral cutting speeds of :—bottom spindle, 6,300 ft. per min.; side spindle, 6,300 ft. per min.; top spindle, 7,800 ft. per min.

The extra speed given to top cutter spindle is because this cutter spindle has the heaviest work to do, having to reduce the timber to an even thickness and a given size.

Surface planing machines . . . 5,000 to 5,500 ft. per. min. of cutting circle.
Surfacing and thicknessing machines (combined) 5,000 to 5,500 „ „ „

The above instances are for average cases, and may be accepted as good standard practice at the present time.

Tenoning Machine (light) 4,500 to 5,500 ft. per min. of cutting circle.
„ „ (heavy) 3,500 to 4,500 „ „ „ „
Fret Saws . . . . 1,200 revs. per min. 1½ in. stroke.
Carving Machines (light) . . 8,000 revs. per min. of spindle.
Single Spindle Dovetailing Machines 5,000 to 6,000 revs. per min. of spindle.
Boring Augers (ordinary):

Up to 1 in. diam., 1,800 to 2,000 r.p.m. Up to 2 ins. diam., 1,000 r.p.m. Up to 3 ins. diam., 750 r.p.m.

Emery Wheels, for saw-sharpening, etc., 4,500 to 6,000 feet periphery velocity.

Force Required to Punch Holes and Cut Plates.

If W = maximum force in lbs. required to punch hole,

t = thickness of plate in ins.,

then

$$W = 190{,}000dt$$

for structural steel, soft iron, boiler and steel plate.

As W varies as dt, the same machine and power would punch a $\frac{3}{4}$-in. hole in a $\frac{3}{4}$-in. plate, as would punch a $2\frac{1}{4}$-in. hole in a $\frac{1}{4}$-in. plate, since $\frac{3}{4} \times \frac{3}{4} = 2\frac{1}{4} \times \frac{1}{4}$.

If F = force required to shear plates with straight knives inclined at an angle $\alpha°$ with each other, then

$$F = 30{,}000\, t^2 \cot \alpha°.$$

An approximate rule for finding the force required to cut metal by punching or shearing is

Force = 80 per cent. of the tensile strength of a bar having a cross-sectional area equal to the area of the metal cut.

The side thrust on a shearing blade when it is dull and the plate is tipped may be taken as equal to 1·5 W, when W is the force acting normal to the plate.

Flat punches should always be used when the thickness of the plate is greater than two-thirds the diameter of the hole. If the thickness is less than half the hole diameter, much less force is required when a shearing punch is used. Shearing punches are also recommended for cases where a large number of holes are to be punched close together, because they do not distort the plate as much as flat-ended punches.

The diameter of a punched hole is equal to the diameter of the punch, but if there is an appreciable clearance between the punch and the die, the hole will be conical.

(Lewis Jenkins, University of Cincinnati.)

Power Losses in the Machine Shop.

Engine friction, 10 per cent.; line shafting, 15 per cent.; belts and pulleys, 15 per cent.; empty machines, 15 per cent.; cutting metal, 45 per cent.; total, 100 per cent. Even this efficiency is probably only realised when everything is working at full capacity.

Of all metals cut in the machine shop, cast-iron is said to absorb least power per unit of weight removed, while the harder steels require the maximum. Thus, to remove 1 lb. of cast-iron per hour requires the continuous expenditure of from 0·15 to 0·30 h.p., or, say, an average of $\frac{1}{40}$ h.p., where steel calls for $\frac{1}{25}$ h.p.

An average lathe will cut 10 to 20 lbs. of cast-iron per hour and absorb ¼ to ½ h.p. in useful work, and similarly steel will be removed at a rate of 5 to 10 lbs. and demand ½ to ⅔ h.p. Much also depends on the condition of the machine itself, which may increase its demand for power from 0·36 to 2·3 h.p. very quickly, simply from a dry main spindle.

A lathe run without cut may absorb 0·04 to 0·16 h.p., and this will amount up to 0·3 or 0·4 simply by tightening the work in the centres. A large 84-inch wheel lathe has been found to absorb 1·75 h.p. and when cutting, 5·8 h.p. on heavy work.

Planers use ·035 h.p. per pound of cast-iron removed per hour, and 0·065 h.p. per pound of steel, and it may remove 20 lbs. of soft steel or 30 lbs. of cast-iron per hour. Ordinarily, however, the machine would not consume 1 to 1·3 h.p., as these figures would indicate, but only about ½ h.p. Adding for the machine will probably show an average power of 1·0 h.p. in ordinary work.

TOOL STEEL AND TOOLS.

Treatment of Carbon and High-Speed Steel Tools.

CARBON STEEL.

The term carbon steel has been generally applied to 'straight carbon' and 'carbon-alloy' steel. The former is obtained directly from blister steel, which is melted in crucibles, poured into a cast-iron mould and cooled. Subsequently the ingots are retreated, hammered and rolled to the desired shape and size. The carbon-alloy is obtained by adding small quantities of tungsten, chromium, silicon, etc. The latter steel has distinct advantages over the former in that it is easier to forge, is less liable to failure in hardening, and has a greater cutting capacity. The chemical composition of a representative tool of the latter class is given below.

Chemical Composition of Ordinary Carbon Tool Steel.

Carbon, 1·1 per cent.; manganese, 0·35 per cent.; silicon, 0·17 per cent.; phosphorus, 0·018 per cent.; sulphur, 0·015 per cent. The sulphur and phosphorus are undesirable quantities, the former producing brittleness when hot or 'hot shortness,' and the latter 'cold shortness.' The silicon and manganese facilitate melting and forging, and improve the quality of the finished steel. The hardness of the steel chiefly depends upon the carbon contained in it. The various tools contain different percentages of carbon to suit the work they have to do. Thus, tools subject to sharp blows should contain a low percentage of carbon, and keen-edged tools a high percentage. The carbon contents for different classes of tools are as follows:—

Tools such as snaps, hammers, drifts, stamping dies, contain about 0·65 per cent. carbon. Smiths' tools, hot and cold sets, swages, punches, shearing blades, cold chisels, miners' drills, minting dies, contain about 0·7 to 0·8 per cent. carbon.

Large milling and other circular cutters, very heavy lathe tools, drills, taps, screwing dies, reamers, contain about 1 per cent. carbon, whilst the smaller and lighter varieties of cutters, turning and similar tools, drills, and reamers, contain from 1·1 per cent. to 1·3 per cent. carbon.

HARDENING.

Hardening is effected by heating the tool to a colour between a dull and cherry-red; that is, between a temperature of 1,365° F. (740° C.) and 1,400° F. (760° C.), and immediately quenching it in water, or in a suitable bath so that the temperature is at least lowered to 390° F. (200° C.), but preferably to a normal temperature of about 60° F. Some tools, depending on their composition, will harden a few degrees below 1,365° F. and some require a slightly higher temperature. The upper limit must not be exceeded, otherwise the steel becomes coarse and weak, but providing the temperature is kept within the range the steel is apparently uninjured. The lower hardening temperature, or what is called the 'critical point,' must be reached, otherwise the steel after quenching will be too soft for cutting metal.

TEMPERING.

This is done by heating to a temperature between 390° F. (200° C.) and 600° F. (315° C.) and cooling slowly. The higher the tool is heated within this range the softer it becomes. It is of the utmost importance that the tool should be uniformly heated, and quenched, otherwise some parts will be harder than others and internal stresses set up which will produce warping and cracking. To minimise any irregularity in heating formed cutters, modern practice is to heat these in a bath of molten metallic salts which is maintained at a constant temperature by gas or oil jets.

ANNEALING.

Irregular annealing is responsible for much warping and cracking, and it is advisable that formed cutters should be carefully annealed before forging, and even again before being hardened, so as to remove any initial strains and strains produced in machining. These precautions as to annealing should be observed with all classes of steels.

* See also METALLURGY, Section XL.

Self-Hardening or Mushet Steel.

This class contains on the average about 5·5 per cent. tungsten, 2 per cent. carbon, 1·5 per cent. manganese, 1 per cent. silicon, and 0·4 per cent. chromium. As in the case of high-speed steels the proportions of the various elements have a most pronounced effect on the quality.

The self-hardening property of this steel principally depends upon a high percentage of manganese or chromium in combination with tungsten or molybdenum. Such steel is hardened by heating it to a bright red colour (about 1,500°F.) and allowing it to cool. If heated much above this temperature it will crumble in forging, and its cutting capacity is permanently impaired. When cold it is very hard, and retains its cutting edge much better than carbon steel tools.

High-Speed Steels.

High-speed steels are also self-hardening, but are usually forced in cooling by an air blast or by quenching in oil or other medium. The elements of this steel are very similar to some of the older types of self-hardening steels, but they contain much more tungsten and chromium and about one-third the quantity of carbon. Several old self-hardening steels had all the desirable elements and proportions of a high-speed steel, and it was due to the supposed 'overheating' of such steel that its latent cutting capacity was revealed, and not to any new properties or proportions.

Broadly speaking, there are two classes of this steel, viz., *ordinary* and *new* high-speed steel, and for these Mr. F. W. Taylor gives the following chemical composition :—

Chemical Composition of Ordinary and New High-Speed Steels.

Class of Steel.	Tungsten. Per cent.	Chromium. Per cent.	Carbon. Per cent.	Manganese. Per cent.	Vanadium. Per cent.	Silicon. Per cent.
Ordinary .	8·0	3·8	1·85	0·30	—	0·15
New or modern	18·91	5·47	0·67	1·1	0·29	0·043

The carbon contents in the ordinary high-speed steel is high, and the principal difference between the ordinary and new high-speed steels is that the latter contains a quantity of vanadium. The addition of vanadium raises the 'critical point' and enables the tool to withstand a higher temperature due to an increased speed of cutting. Tools of this steel are harder and retain their cutting edges longer than ordinary high-speed steel tools. They are therefore particularly suitable for cutting very hard metals, such as railway and car tyres, which have become very hard with usage, manganese steel castings, chilled rolls, etc. A tool containing 0·25 per cent. of vanadium lasted twice the time of a similar tool containing no vanadium, whilst Mr. J. M. Gledhill points out that by substituting 2 per cent. vanadium for chromium in a steel, good results were obtained when tried on medium steel, but were no better than the steel containing the much cheaper element chromium.

A steel may therefore be made of the best quality of material, but unless the elements are properly proportioned and care and skill be exercised during melting to ensure a proper mixing and avoid 'dryness' (a brittleness produced by retaining the steel in its melted state for an undue length of time), it may fall short of a first-class steel. As the percentage of the vital elements decrease, the difficulties in successful melting and mixing increase, and the most satisfactory steel to suit the various conditions prevailing in practice can only be obtained by prolonged experimenting.

To Identify High-Speed Steel Scrap.

The spark from high-speed steel ground on an emery wheel is a dark-red spark that is inclined to scatter, while the spark from ordinary carbon steel is much whiter and is not inclined to scatter. The sparks from high-speed steel are about the same colour as from cast iron, but are much finer.

Annealing.

This process is best accomplished by placing the tools in a sealed oven, furnace, or muffle, where they are uniformly heated by radiation. By excluding the air, and preventing the flame impinging on the steel, scaling is avoided and the fine cutting edges preserved. The furnace should be heated in such a manner that in about two hours' time it attains a temperature of 1,544°F. (840°C.), or very slightly higher, and should be steadily maintained at this temperature for about two hours. The heat is then cut off and both furnace and tools are allowed to cool slowly.

To release the furnace during the cooling process some smiths bury the articles in lime, powdered charcoal, soot, or coarse sawdust of some particularly hard wood. The bed in the latter case should be about 24 inches deep and contained in a box having an airtight lid. The articles when dropped on the top of the sawdust and covered with the lid work their way slowly down.

Should such a furnace not be available the tools may be placed in an iron pot or pipe and packed tight with steel cuttings or lime. The pot is then sealed with fireclay and raised to the above temperature at which it is retained for about eight hours before it is placed in charcoal ashes to cool. Good results are obtained from this process, but it is exceedingly slow, and it is doubtful if any advantage is obtained by prolonging the treatment after the annealing temperature has been attained throughout.

Forging.

If a piece has to be cut from the cold bar, this should be done before nicking the bar all round otherwise small cracks are likely to be started. Preferably the bar should be cut through at a forging heat. In forging, heat the tool slowly and uniformly (without the blast) to a dull red, then raise quickly to a bright red or yellow heat (1,800° to 1,900° F.), when it can be easily and rapidly manipulated. To prevent cracks, hammering should cease as soon as the heat has fallen to a medium red (about 1,400° F.). The steel may be rapidly reheated from this temperature for subsequent forging without any ill-effects. On account of ease and economy in forging, together with general utility and efficiency in cutting, a roughing tool is recommended. This form of tool can be quickly forged by first cutting the required length from the bar and afterwards forming the front, side and top angles by simply jumping the nose. This shape gives the minimum of waste material.

Hardening.

A temperature of 2,000° F., which is ruinous to other steels, gives this steel the property of resisting abrasion at a higher temperature. It is therefore capable of retaining its cutting edge at the high temperatures accompanying high speeds of cutting. This quality, which has been termed 'red hardness,' is not possessed by other steels. In hardening high-speed steel it is slowly pre-heated (in order to obtain a uniform heat throughout) to a medium red (about 1,550° F. then quickly raised to the following temperatures :—Ordinary high-speed and molybdenum steel from 2,000° F. to 2,200° F. (yellow or lemon heat), vanadium steel from 2,200° F. to 2,350° F. The lower figure is recommended for oil hardening and the higher for air hardening. When the heating is done in the smith's fire, obtain a good, deep bed of small coke or soft coal and pre-heat the tool by laying it in the fuel at some distance from the hottest part till the fire is thoroughly blown up. To ensure uniformity the tool during both stages of heating should be frequently turned round. Some smiths prefer to obtain final heat by placing the tool within a piece of scrap piping which is maintained at the required temperature by the surrounding fuel on the hearth. Except for the simplest form of tools such as those of the lathe type, the smith's hearth is unsuitable. Formed tools such as milling cutters, hobs, reamers, etc., are best heated in gas, oil or coke-fired muffle furnaces. Modern furnaces for this work usually have two chambers, i.e., an upper in which the cutter is pre-heated, and a lower chamber in which the cutter is raised to the final temperature. Another method of raising the cutter to its final heat is to immerse it in a mixture of molten metallic salts (barium chloride, etc.). The bath is heated and maintained at any desired temperature by passing an electric current through it. As the heat generated varies as the current passes through the circuit the arrangement is ideal for obtaining uniform conditions. The first cost, however, is large, and attempts have been made to obtain similar results from gas-heated salts in graphite crucibles. Trouble arises in the latter device through oxidisation : particles of iron oxide floating on the surface are inclined to adhere to the tool and produce soft spots.

Many have an idea that it is impossible to injure high-speed steel by overheating. This is certainly not the case. If an ordinary high-speed steel tool be heated to 2,400° F. and cooled in an air blast, its fracture will show a very coarse grain.

Once the final temperature has been attained the tool should be immediately withdrawn, as prolonging the treatment, even without raising the temperature, injures the steel and reduces its cutting capacity.

'Pack' Hardening.

It requires a man with considerable experience to harden successfully large high-speed steel milling cutters or hobs, and also a first-class furnace designed for this purpose. The disaster attending repeated attempts to do this has caused some hardeners to resort to 'pack hardening,' and possibly the desire to get away from scaling effects has also had something to do with this innovation. In this process about a 1-in. layer of charcoal ($\frac{1}{4}$-in. lumps) is made in the bottom of a cast steel box. Over the charcoal is placed a perforated plate which supports the cutters, but there is no charcoal against the cutters, etc. When several cutters are packed in the box these are separated by asbestos. When charged a lid is placed on the top of the box and sealed with clay. The box is then placed in a suitable furnace and the temperature raised to 1,250° C., and held at that for an hour or two, depending on the time required to thoroughly heat the contents. The cutters are cooled in hot oil or metallic salts in the usual way.

The object of the charcoal is to consume the free oxygen in the box before the steel gets sufficiently hot to scale. Scale is oxide of iron, and will not form if there is no free oxygen, so that however hot the steel may get, it cannot scale.

Tools or cutters which have to be rehardened after having been in use should be annealed prior to this operation, and thereby relieve the internal strains.

Before attempting to harden steel, it is advisable to remove by grinding or machining the black scale (oxide of iron) on the bar or forging, as immediately adjoining it is a thin film of decarburised material, which cannot be altogether avoided in the manufacture, and which will not be hardened.

Quenching.

Uniform cooling is just as essential to the successful treatment of steel as uniform heating, providing this is done it does not matter whether the medium is an air blast, oil, or water. To quench high-speed steel in water, however, is liable to produce cracks, and this is particularly the case in formed cutters where it is impossible to obtain uniform cooling by such a rapid process. Tools of the lathe type are usually cooled in a strong air blast, whereas formed cutters are generally quenched in a bath of salts about 500° F. or in rape or whale oil at a temperature of 250° F. and afterwards cooled in cold oil. The oil cooling gives a clean smooth surface to the cutter.

Quenching Medium.

After heating, it is usual to quench this steel in water, brine, oil, metallic salts, molten lead, etc., depending on the size of the tool or purpose for which it is intended. The function of the medium is to abstract rapidly the heat from the steel, as it passes through the critical range, and nothing more than this. Water therefore, on account of its mobility, makes an excellent cooling medium. The colder the water, and the more rapidly it is circulated, the greater the hardness will be. Cold water which has not had the chill taken off is very liable to produce cracks, whilst with boiling water it is impossible to harden at all. In the latter case a jacket of steam forms between the tool and the water, and cooling is retarded. It follows, therefore, that different degrees of hardness can be obtained by having the water at different temperatures. To raise the boiling-point, salt (as much as the water will carry) is frequently added, and for general purposes such a mixture at 40° C. (104° F.) is quite good. Keep the liquid clean and free from grease or oil. A great deal of nonsense has been spoken and written on the relative merits of quenching mediums, and to Mr. S. N. Brayshaw, M.I.Mech.E., especial credit is due for exploding many of the fantastical theories on this subject. According to Mr. Brayshaw, the ability of a liquid to bring a body immersed in it to its own temperature depends upon the following properties: (1) Specific Gravity, (2) Specific Heat, (3)Boiling-point, (4) Thermal Conductivity, and (5) Fluidity.

Specific Gravity.—The specific gravity determines the weight of liquid in contact with the tool being quenched.

Specific Heat.—The heat required to raise the temperature by a given amount, of a pound of different liquids varies enormously. If a red-hot tool weighing 1 lb. be immersed in a gallon of water weighing 10 lbs., the water quenches the tool, and its own temperature is raised about 12° C. in so doing, but if immersed in 10 lbs. of mercury, which has a very low specific heat, the temperature of the mercury rushes up more than 200° C.

Boiling-point.—When a tool is quenched in water or oil, a jacket of steam or vapour may be instantly formed, and this retards the cooling very greatly. Liquids, like solids, vary in their ability to conduct heat, but a deficiency in this respect may be compensated for by motion in the liquid.

Fluidity.—The ability of a liquid to circulate freely is one of the most important factors as regards quenching. The agitation may be caused by moving the tools about rapidly in the liquid, or by directing jets upon them.

Water.—The fact that its thermal conductivity is very low is counterbalanced by its fluidity. The higher the temperature of the quenching water, the more nearly does its effect approach that of oil, and if boiling water is used it will be even more gentle in its action than oil.

The Boiling-point of Water in relation to its Quenching Capacity.

If ordinary tool steel could be very rapidly quenched by any means to a temperature of 100° C. it would harden perfectly; but water at 100° C. (that is, boiling water) is incapable of quenching steel rapidly, and the nearer the boiling-point is approached, the worse it becomes for quenching purposes. When a red-hot tool is immersed in water, steam is generated around the tool, keeping the water away from it and interfering with the quenching. If the water is boiling, the tool is completely jacketed.

The Effect of Stirring during Quenching.—The tools cool much more quickly if they are stirred, or, what amounts to the same thing, if the water is projected in a stream upon the tools.

The Addition of Acid or Salt to the Quenching Bath.—The addition of sulphuric acid increases the conductivity of the water, but the gain from this cause is small in comparison with rapid circulation of water.

It is sometimes stated that sulphuric acid is added to prevent hardening cracks, but this is inconsistent with the other idea that it is used to obtain a greater degree of hardness. If the liability to crack is reduced, it is because the acid has made the quenching bath more gentle in its action, and thereby reduced the hardness.

Seasoned Water for Quenching.

Water ordinarily contains air dissolved in it, and this air is expelled when heat is applied. For this reason water which has recently been boiled and allowed to cool again, may be expected to quench the steel with greater rapidity and uniformity.

Quenching in Oil.—It is necessary in some cases to quench in oil, although it should be avoided wherever possible. Oil to one specification is not always the same, and even if it were, considerable changes are brought about with use, and its quenching power soon becomes different to that of new oil.

Quenching in Fusible Salts.—The ideal quenching liquid would be one which, at a temperature of say 100° C., had sufficient quenching power to cool steel so rapidly that it would harden thoroughly.

Experiments have been made by Mr. Brayshaw with chlorides, fluorides, carbonates, and other compounds, in order to find a 'melt' for quenching.

Such a 'melt' or mixture of salts differs from that used in the salt bath as ordinarily understood, in the fact that the salt bath commonly consists of a mixture of chlorides which are liquid at a red heat, and in which tools are immersed in order that they may be raised to the temperature necessary for hardening. The 'melt' now under consideration is primarily not for heating, but for cooling the tools, although it may be remarked incidentally that such a 'melt' may usefully be applied for the tempering of tools after they have been hardened.

The endeavour was to find a mixture, free from water, which would be liquid at a temperature as low as possible, have a high specific heat, and should be obtainable at reasonable prices.

A mixture known as 'Quenchite' resulted. It is liquid at 135° C. (275° F.), and at this temperature it is almost as fluid as water. It quenches steel very rapidly, has a very high boiling-point, and consequently the liquid is in direct contact with the steel almost from the moment of immersion.

The temperature of 135° C. is, however, so high that 'Quenchite' is only suitable for hardening small or thin articles. Small cutters and long reamers or taps can be quenched in it to give a glasshard surface, and with practically no warping or change of shape, but it is not sufficiently severe in its action to give the necessary hardness to a sufficient depth in the case of large tools in which there is a considerable body of steel behind the cutting edge.

Manner of Quenching.

In order to secure uniform cooling and absence of warping, all sorts of dodges are resorted to by hardeners. In the case of small articles, these are dipped bodily into the medium, so that the whole is cooled at the same instant.

Twist drills, taps, reamers, etc., are dipped vertically, and to move these sideways in the bath would distort them. To avoid this, the medium is stirred with a stick so as to give it a rotary motion, and the drill or tap is dipped in the centre of the swirling liquid, and moved vertically upwards and downwards. Blades for lawn mowers, shear blades, and similar things should be gripped in the centre with the tongs, dipped edgewise in the liquid, and moved edgewise through it, or the liquid itself may be agitated. Sometimes the blade is held between two pieces of iron slightly larger than the blade, and the whole dipped together. A hammer face, if dipped in the liquid, would cool at the edges before it did at the centre, and for this reason a sprayer or jet of water directed on the centre of the face is preferred.

Tempering.

May be accomplished by placing the cutter in a gas stove and raising the temperature to about 500° F., when the gas is shut off and the whole allowed to cool slowly.

Some prefer to first reduce the temperature of formed cutters to about 800° F. in the air blast, then to plunge the same in tallow at 200° F., when the temperature is again raised to about 500° F. and the whole allowed to cool.

Grinding.

The tool should be ground by *hand* pressure on a *wet* sandstone wheel. If it is necessary to use the emery wheel, the tool should be roughly ground to shape after forging, and finished on the wet sandstone after hardening.

Hardening High-Speed Steel Tools *

(1.)

The heat treatment usually prescribed for hardening high-speed steel tools consists in heating the nose of the tool slowly and uniformly to a red heat, then rapidly to a white or welding heat, at which the steel commences to fuse and blister, and then cooling either rapidly or slowly in air or quenching in oil.

The Department of Scientific and Industrial Research desires to direct the attention of users of high-speed steel tools to the fact that uniform and improved results may be obtained by carrying out the hardening process in two stages in accordance with the instructions given below. This treatment is the outcome of the researches of F. W. Taylor in America, and of Carpenter, Edwards, Dempster Smith, and others, in this country. It may be stated that the adoption of this process for the hardening of special tools required for a most important purpose in connection with the war has yielded consistently uniform results, which are immensely better than the best results previously attained. The procedure given below is that adopted by Mr. Dempster Smith in the researches on tool steel carried out in the Manchester School of Technology for the Manchester Association of Engineers, with the aid of a grant from the Research Department.

First or High Heat Treatment.—Thoroughly preheat the tool to about 800° C. (1,472° F.), and transfer immediately to a high temperature furnace at a temperature of not less than 1,350° C. (2,462° F.) for ordinary high-speed tools, and about 1,320° C. (2,408° F.) for super high-speed steel. Retain it in the furnace until the surface of the tool nose is covered with small blisters slightly larger in size than a pin's head, in the case of ordinary high-speed steel, or until the entire surface of the nose is in a state of incipient fusion, or in the case of super high-speed steel presents a greasy appearance. The steel in the first case will have attained a temperature of about 1,320° C. (2,408° F.), and in the second a temperature of 1,290° C. (2,354° F.). Remove the tool and cool in an air blast of large volume.

Second or Low Heat Treatment.—Reheat the tool hardened as above to 570° C. (1,058° F.), for half an hour for tools with sections of half an inch square, or longer in the case of larger sections, and cool in an air blast or in still air. If carefully handled a higher temperature of about 610° C. (1,130° F.) may be adopted if the treatment is limited to ten minutes for tools of the smaller section, and slightly lower for those of larger section. All temperatures for the first and second heat treatment should be measured by means of a pyrometer, and care should be taken to ensure that the portion of the tool under treatment is uniformly heated throughout to the required temperature.

(2.)

The prevailing method of heating tools in ordinary gas furnaces, even when the utmost care is exercised, does not yield uniform results as regards cutting efficiency. The following procedure will be found to yield uniform results :—

First or High Heating.—The preliminary heating to about 800° C. (1,472° F.) may be carried out in a gas-fired muffle or semi-muffle. Care should be taken at this stage to ensure that the whole of the nose of the tool or the part to be heated subsequently to a high temperature is brought uniformly to the required temperature. The high heating to 1,350° C. (2,462° F.) should be carried out in a gas-fired furnace with a reducing flame so disposed that the heating of the tool is effected more by radiation from the heated surfaces of the furnace than by contact with the gases. It is important that the tool shall not be brought directly in contact with the burning gases. Detailed drawings of a furnace to fulfil the above conditions will be furnished on application to the Department.

Second or Low Heating.—This may be carried out at 570° C. (1,058° F.) in a gas-fired muffle or in a lead bath.

Tool Steels.

The treatment given above may be applied to steels containing tungsten, chromium, or vanadium, and generally to ordinary brands of high-speed tool steel. It may be found that certain special steels require a modification of the above treatment, particularly of the temperature required for the second heating ; in such cases users are advised to refer to the makers of the steel, or, if possible, to investigate the matter for themselves.

Results.

When the heat treatment described above is carefully carried out, it will be found that the cutting efficiency of the tools is high and is maintained throughout the entire length of the nose, and that no further heat treatment is necessary after grinding (see page 1071). The second heat treatment toughens the steel, and its advantage is very pronounced when working tools at high speeds

Furnace.

A type of gas muffle recommended is shown by fig. 58.

Oil Fuel Heating Systems.

(Abstract of paper read before the Royal Society of Arts by Mr. A. F. Baillie.)

Billet-heating furnaces using the air-jet system, with air and oil preheated by the exhaust gases showed a consumption of 9 lbs. of oil per 100 lbs. of metal heated for drop stamping. In heating furnaces for nut-making, the consumption was found to be about 4 lbs. of oil per 100 lbs. of metal heated, and for bolt-making about 4½ lbs. A test on a bolt-making furnace 9 ins. by 12 ins. by 20 ins. resulted in 400 to 500 gross of bolts of from ¾ in. to 1 in. per week on a consumption of 300 gallons of oil. Rivet-heating tests show for some furnaces on this work a consumption of 10·3 lbs. of oil per 100 lbs. of metal heated. For pot furnace work a tilting crucible furnace takes about 10 lbs. of oil per 100 lbs. of gunmetal melted, an open-hearth furnace about 11·8 lbs., and a lift-out furnace about 12·5 lbs. of oil. Stock converter furnaces for melting cast iron and steel-making take about 15 lbs. of oil per 100 lbs. of metal for melting only, but the total, including lighting and heating up, runs to about 40 lbs. In glass works the tank type of furnace takes about 37 lbs. per 100 lbs. of finished glass. An Italian plant of open-hearth Siemens basic furnaces of 55 tons capacity, with an output of 150 tons of steel per 24 hours per furnace, the oil consumption ranges from 16·5 tons to 18·75 tons, or from 11 lbs. to 12·5 lbs. per 100 lbs. metal. The air pressure for atomisation was 4 kilos. per sq. centimetre.

The Burdon Oil-Gas System.

In this system the oil fuel, first very finely atomised and intimately mixed with a large volume of air at *low pressure*, is converted into gas in a small retort, and from the retort the gas is delivered into the furnace (through pipes of varying diameters), where, by the regulation of the air supply, any desired flame can be obtained. The intimate mixture of gas and air produces very high heating results, the full calorific value of the fuel being obtained.

The temperature is regulated by adjusting the valves which control the oil and air supplies.

By proper regulation of the air the fuel burns with a non-luminous Bunsen flame, and complete combustion with entire absence of smoke is easily secured.

The air and fuel can be supplied in any proportion desired, so that the flame in the furnace may be either reducing, oxidising, or neutral as desired.

A furnace 10 feet by 6 feet can be brought from cold to approximately 3,000° F. in less than three hours.

The Burdon system can be used for billet heating, slab and bloom heating, chain making, all kinds of welding and forging, case-hardening, tube heating, rivet and bolt making and heating tin smelting, tool heating, horseshoe making, etc., also for steam raising, superheating, glass melting, metal melting, assaying, insulator making, etc.

Later developments effected in this system enable any quality of liquid fuel, either heavy crude fuel oil, or such as a mixture of 50 per cent. pitch and 50 per cent. of a tar-oil, or, alternatively, any of the lighter fuel oils, such as creosote and gas oils, etc., to be used with results giving high heating efficiency and economy in oil fuel.

The furnaces, which are made in various sizes, from small portable rivet heaters up to large forging types, consist of a combined generator and heating chamber. The oil is contained in the tank, from which it flows, without pressure, to the atomiser and the hot carburettor, where it is vaporised and intimately mixed with the air supply, forming a combustible gas, which passes to the actual heating chamber. The waste gases from this chamber pass through flues to the upper chamber to maintain a sufficient heat in the carburettor, to gasify the oil fuel.

Among the advantages claimed for this system are:

Cleanliness of installation and economy of space.

The producers can be applied to existing furnaces with a minimum of alteration or reconstruction.

Remarkably small fuel consumption, and no coal or coke trimming, stoking, or removal of clinker or ashes.

The cost and time of working is less than for coal or coal gas-fired furnaces.

Compressed Gas System.

There is an optimum pressure for the various applications of gas, and in order to meet this the gas can first be compressed to (say) 280 inches head of water (about 10 lbs. per sq. inch) which can be controlled at the various furnaces, etc., to the pressure required at each place. Pressures for typical work are as follows:—For melting tin or solder 65 inches; small hardening furnaces 65 inches; for blueing steel 65 to 80 inches; for the steel tempering lead pot 150 inches; while for melting metals at 2,000° F. to 2,600° F. 200 inches should be used.

Soldering irons can be heated at 65 inches pressure, which pressure is also convenient for the lighting.

With gas at 2*s.* per 1,000 and coal at 20*s.* per ton, there is little to choose between gas and coal firing as regards fuel costs. As regards cleanliness, uniformity, wear and tear of pots, and accuracy of control, the advantages are however in favour of gas, and in many cases with properly

GAS MUFFLE FURNACE FOR HEATING HIGH-SPEED TOOLS.

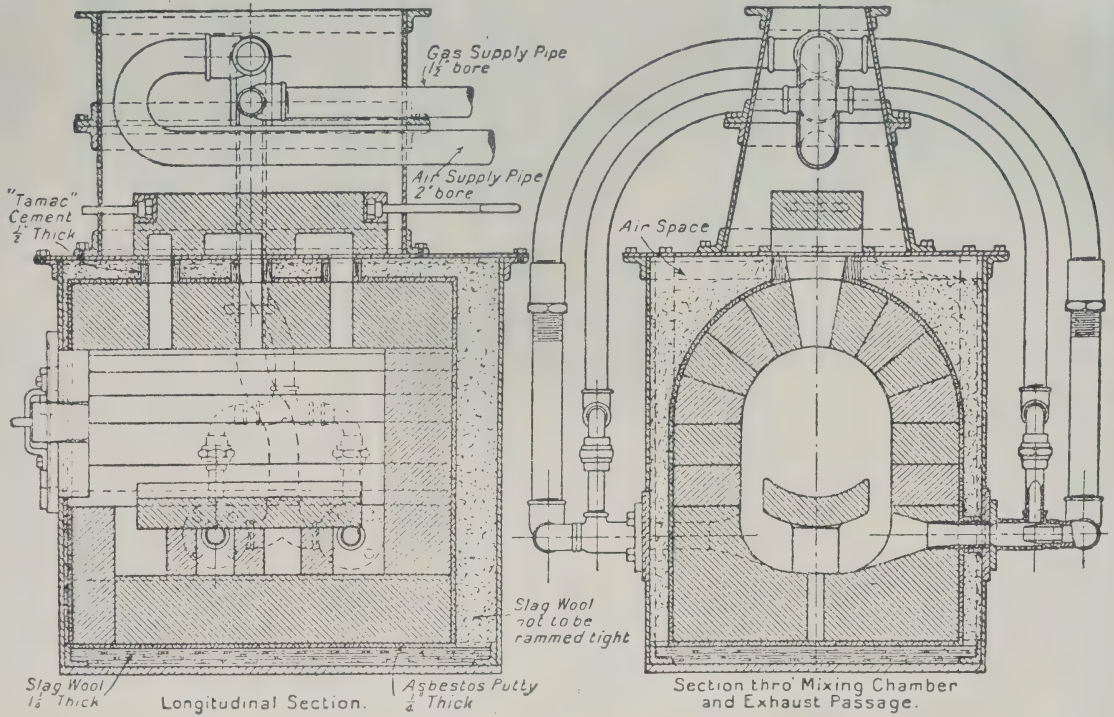

FIG. 58.

designed furnaces it is greatly superior to coal, not only from the point of view of cost, but from convenience, reliability, and ease of manipulation. There is also a large saving of time taken and space occupied by a gas furnace as compared with a coal furnace of similar power, factors of great importance when increased output is called for.

Low-pressure gas with air blast is largely adopted.

TABLE OF COMPRESSOR DATA.

Capacity of Compressor. Cub. ft.	H.P. required.	Floor Space. Ins.
100	·12	18 by 7½

Colours of Tempered Steel.

The *tempering* in this case relates to lowering the degree of hardness obtained by plunging the steel when heated to a cherry red (1,650° F., 899° C.) in cold water :—

Colour.	F.°	C.°	Colour.	F.°	C.°
Very pale yellow .	430	221·1	Dark purple . .	550	287·8
Straw yellow . .	460	237·8	Clear blue . . .	570	298·9
Brown yellow . .	500	260·0	Pale blue . . .	610	321·1
Bright purple . .	530	276·7	Blue tinged with green .	630	332·2

Composition of Quenching Baths for Tempering Cutting Tools.

Fused nitrates of potassium and of sodium are too high in temperature for certain cutting tools, as they do not permit of cooling below 328° F. (220° C.). Mixtures of nitrate of potassium and of nitrate of sodium can, however, be employed, and a series of mixtures, fusing at different temperatures, be obtained.

Temperature.		Nitrate of Potassium.	Nitrate of Sodium.	Temperatures.		Nitrate of Potassium.	Nitrate of Sodium.
F.°	C.°			F.°	C.°		
536	280	0 parts	100 parts	279	137	55 parts	45 parts
446	230	20 „	80 „	293	145	60 „	40 „
342	172	40 „	60 „	437	225	80 „	20 „
293	145	50 „	50 „	635	335	100 „	0 „

Higher temperatures than 752° F. (400° C.) cannot be obtained with these mixtures. In steels where without extreme hardness absolute absence of brittleness is necessary, 932° F. (500° C.) to 1,112° F (600° C.) are temperatures more suitable. The following bath gives, on fusion, a temperature of 932° F. (500° C.) :—

Sodium chloride, 1 part; potassium chloride, 1 part; fused calcium chloride, 2 parts; hydrated barium chloride, 1 part; hydrate strontium chloride, 3 parts.

For a bath fusing at 1,292° F. (700° C.) the following mixture may be used :—

Hydrated boric acid crystals, 1 part; silver sand, 1½ part; anhydrous potassium carbonate, 1 part; anhydrous sodium carbonate, 1 part.

When prolonged treatment is required, a little cyanide or charcoal may be added to prevent superficial decarburisation; but, in view of the strongly cementating action of cyanide, this salt must be used with caution.

QUENCHING LIQUIDS.

When hot steel is continually dumped into a tank of oil, the lighter and volatile oils are evaporated and finally only the heavier oils will be left. When the oil becomes thick, it will not take the heat away from the steel rapidly; consequently, the steel will be soft and will not

show the maximum physical properties. To obtain good results, the quenching liquid should be of a constant specific gravity and maintained at a temperature of 70° to 90°, but the exact temperature at which the bath is maintained does not matter so much if it is always the same. To ensure the best results, the bath should always be maintained at a certain specific gravity and at some certain temperature. (*'Machinery,' New York.*)

In hardening and tempering a chisel, the best way, says the *English Mechanic*, is to heat it to a very dull red for a good inch up from the edge, holding the tongs in the left hand, and in the right a rub stone, a piece of broken grindstone or emery wheel, or, failing these, a piece of emery cloth wrapped round a small file. Dip the chisel for about half-an-inch until it just turns black, then withdraw it from the water and let it rest against the side of the pail, so as to steady it; rub it sharply with the stone, so as to brighten it, and watch the colour as it runs down from the part which is still hot, and when the edge is of a deep plum colour, verging on blue, dip it right out.

Grinding.

1. The tool should be forged roughly to shape and ground to the requisite contour by means of a composition wheel (preferably dry) without any lubricant being applied. The heating of the tool during grinding at this stage is not of any importance.
2. After shaping, the tool should be subjected to the two heat treatments indicated (page 1067).
3. It is advisable to finish-grind with a copious stream of water playing on the nose of the tool. If reasonable care to avoid heating be exercised, the tool may be ground on a composition wheel running in water.

Shape of Tool for Roughing Purposes.

The durability or length of time a tool will continue to cut under constant conditions as to feed, speed, etc., increases with the nose radius (fig. 59). The tendency to chatter, however, limits

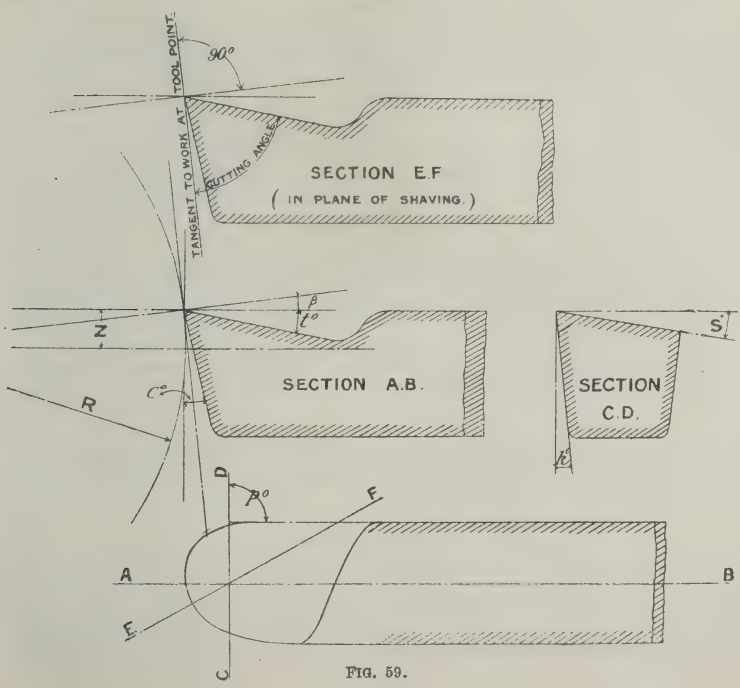

Fig. 59.

the extent to which the nose radius may be increased, and a round-nosed tool having a radius of $\frac{1}{2}$ in. to $\frac{5}{8}$ in. has been found to give the most satisfactory results for the general run of work. With work of a springy character a smaller nose radius may be required. The durability is also affected by the cutting angle, *i.e.*, the angle between the cutting face of the tool and the tangent to the work or 90° minus the top rake angle. The cutting angle is increased when the tool edge stands above the centre of the work, by an amount equal to the angle contained between the cutting edge of the tool and the axis of the bar.

The cutting angles which give the greatest durability to tools for roughing purposes are as follows :

Material.	Cutting Angle.	Material.	Cutting Angle.
Soft steel . . .	65°	Soft cast iron . .	70°
Medium steel . .	70°	Medium cast iron .	75°
Hard steel . .	80°	Hard Cast Iron . .	85°
Nickel steel . .	80°	Brass . . .	85°
Manganese steel . .	85°	Hard gunmetal . .	85°

The above angles are measured in a plane at 45° to the length of the tool which is approximately the plane of the shaving. The side and front clearance angles for tools with cutting edges on the line of centres need not exceed 6°. The shape of the tool recommended is shown below.

Front top rake ($t°$) ; height above centre (Z) ; front top rake (reduced to centre) ($\beta + t°$) ; side top rake ($S°$) ; front clearance ($C°$) ; radius of work (R) ; angle (β) ; front clearance (reduced to centre) ($C° - \beta$) ; side clearance ($k°$).

Steel Tool Shanks.

By the ordinary method of welding, or securing by other means, high-speed steel tips to ordinary steel tool shanks, the shank is weakened considerably at the point where the high-

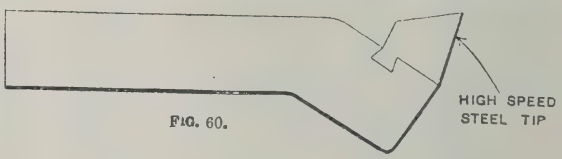

FIG. 60.

speed tip is applied, owing to the shank being cut away to accommodate the steel tip. In the J.B.R. system (the *J.B.R. Tool Co., Ltd., Longsight, Manchester*), fig. 60, the shank retains its original strength, the steel tip being held in a dovetail slot and brazed in position by a method which renders the two materials, when heat-treated, absolutely homogeneous at the joint.

The tools, which are stocked in a range of thirty-nine different shapes, each shape being manufactured in four sizes and two heights, are being largely used.

Sharpening-angles of Wood Machine Cutters.

Adzing soft wood across the grain, 30° ; planing machines, ordinary soft wood, 30° ; gouging and ploughing machines, 30° to 35° ; hard-wood tool-cutters, 35° to 40°.

Cutting Speeds for Carbon Steel Lathe Tools.

The following table gives the appropriate cutting speeds for different depths of cuts and traverses when roughing out with carbon steel tools of the lathe type, having a nose radius $\frac{1}{8}$ in., on various metals. When finishing soft, medium, and hard steel the cutting speeds which may be used are 20 ft., 15·5 ft., and 11 ft. per minute, whilst for finishing soft, medium, and hard cast iron the cutting speeds are 24 ft., 19 ft., and 14 ft. per minute in the order given. When finishing brass and copper, speeds of 80 ft. and 150 ft. per minute respectively should be adopted. The finishing cut should not exceed $\frac{1}{32}$ in. in any case. (*Dempster Smith.*)

TABLE OF CUTTING SPEEDS IN FEET PER MINUTE FOR CARBON STEEL LATHE TOOLS.

For ordinary Mushet steel the above speeds may be increased from 33 per cent. in the case of the lighter cuts to 50 per cent. for the heavy cuts.

The following table gives the revolutions per minute for different cutting speeds and diameters of work or cutters:—

RELATION BETWEEN REVOLUTIONS, CUTTING SPEEDS AND DIAMETERS OF WORK.

Cutting Speed in Ft. per Min.	Diameter of Work or Cutter, in Inches.

CUTTING WITH ORDINARY AND HIGH-SPEED STEEL.

Steel.

Trials showed that 20 ft. per minute with a cut of $\frac{1}{16}$ in. by $\frac{1}{8}$ in. is the superior limit of speed for ordinary water-hardened steel operating upon Whitworth fluid-compressed soft steel;

whilst an ordinary Mushet tool can run at over 30 ft. per minute, with a $\frac{3}{16}$ in. by $\frac{1}{16}$ in. cut upon the same material.

Cast Iron.

The trials on *medium cast iron* showed that 25 ft. per minute is too high a speed with $\frac{1}{16}$ in. by $\frac{1}{16}$ in. cuts; 17 ft. is too high with $\frac{3}{16}$ by $\frac{1}{16}$ in. cuts; and 15 ft. is too high with $\frac{3}{16}$ in. by $\frac{1}{8}$ in. cuts for ordinary water-hardened tool steels. An ordinary Mushet ran for over 20 minutes at 23·6 ft. per minute on a $\frac{1}{16}$ in. by $\frac{1}{16}$ in. cut; whilst it failed at 19 ft. per minute on a $\frac{3}{16}$ in. by $\frac{1}{16}$ in. cut, and at 15 ft. per minute on a $\frac{3}{16}$ in. by $\frac{1}{8}$ in. cut on this material.

In the case of *soft cast iron*, 22 ft. per minute was too high a speed for water-hardened steel taking a $\frac{3}{8}$ in. cut by $\frac{1}{8}$ in. traverse; whilst an ordinary Mushet lasted over half an hour at 31·6 ft. per minute with the same cut upon the same material.

Heavy cuts are much more economical in power, for the waste work is a much larger proportion of the whole work required at light cuts than at heavy cuts. It is probably this fact which has given rise to the commonly accepted opinion that the cutting stress increases with the speed (as instanced by the objections of workmen to increase cutting speeds on account of the anticipated springing of the work), contrary to the results of these trials, which rather show the reverse to be the case. In soft steel, for example, the average horse-power required for actual cutting at $\frac{1}{16}$ in. by $\frac{1}{16}$ in. was 3, while at $\frac{3}{8}$ in. by $\frac{1}{8}$ in. it was 15. The friction horse power of lathe and counter-shaft was about $2\frac{1}{2}$ h.p. The weight removed was about 105 lbs. and 445 lbs. per hour at the light and heavy cuts respectively, so that the weight removed per gross h.p. hour was 19·1 lbs. for the light and 25·3 lbs. for the heavy cut. Neglecting frictional loss, these figures would have been 35 and 29 respectively.

In the case of cast iron, the gain in power at the heavier cuts is still more conspicuous. Here the effective h.p. was 1·7 and 5·5 at the $\frac{1}{16}$ by $\frac{1}{16}$ and $\frac{3}{8}$ by $\frac{1}{8}$ cuts respectively, the waste h.p. being about 2. The weights removed were $42\frac{1}{2}$ lbs. and 198 lbs. per hour, and the weights per h.p. hour were therefore: 11·35 lbs. at the light cut, and 26·5 lbs. at the heavy cut.

These results show that more material can be removed in a given time with a heavy cut at its proper speed than with a light cut at the highest speed which the new steels can take, and that this can be done at a smaller expenditure of gross power per ton of shavings removed.

Variation of Cutting Force with Area of Cut, and of Cutting Stress obtained in the above trials.

For steel the cutting force is simply proportional to the area of cut, and this force has the following approximate values in tons per sq. in.:—

For soft steel (fluid compressed)	. 115	For soft cast iron	51
„ medium steel „ „	. 108	„ medium iron	84
„ hard steel „ „	. 150	„ hard iron	82

Fine traverses take more power than coarse ones.

Cutting stress does not vary much with speed, but tends to diminish.

Special high-speed tool steels will cut twice as fast as ordinary Mushet steel, and more than four times as fast as ordinary water-hardened steel.

(*Proc. Manchester Assoc. of Engrs.* 1903.)

Cutting Speed for High-Speed Steel Tools when Cutting Steel.

An extensive series of experiments have been carried out by the Lathe Tool Research Committee of the Manchester Association of Engineers, when operating on steel under different conditions.* The Committee in many of its investigations selected cutting speeds which would give a twenty minutes life to the tool, but state that for practical purposes and economic considerations, a speed which will give a two hours run is desirable. A relation is, therefore, given between the cutting speed and durability of the tool, and this conforms to the expression:

$$VT^{\frac{1}{3}} = \text{constant},$$

where,

V = cutting speed in ft. per min., and T = duration in mins.

* See Report of Lathe Tool Research Committee, published by H.M. Stationery Office, 1922. Price 5*s*.

The value of the constant varies with the material operated upon and also with the dimensions of the cut. This relationship is of the utmost value, since for a given material, tool, and cut, if the cutting speed V and the life of the tool T be observed, the cutting speed V_1 for the tool to last a time T_1 can be obtained, thus:

$$V_1 = V\left(\frac{T}{T_1}\right)^{\frac{1}{8}}.$$

The change in the cutting speed with time as given by the above law may be better appreciated from its graphical representation in fig. 61, where the appropriate cutting speed is plotted on a base of tool life.

As an example, assuming a tool under test lasts 40 minutes when cutting at 110 ft. per minute,

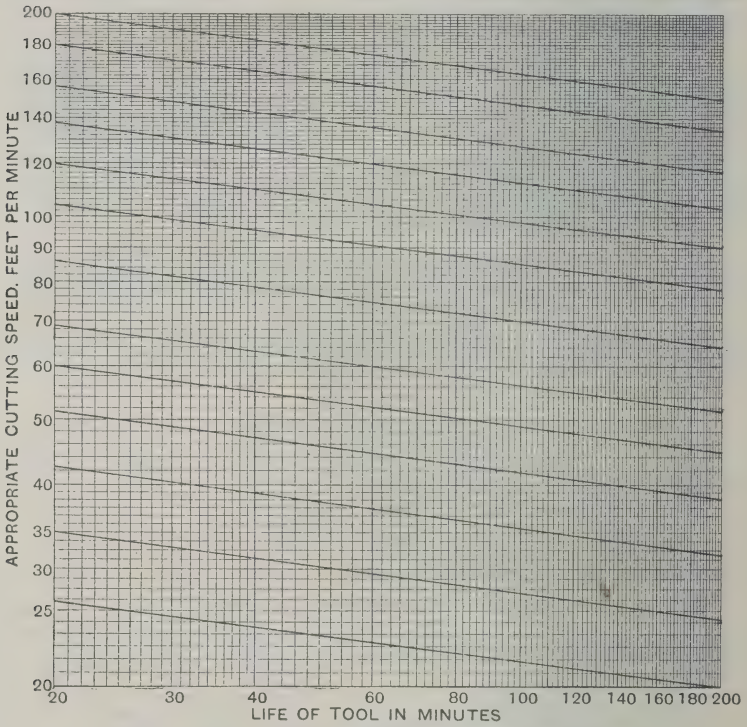

FIG. 61.—Relation between appropriate cutting speed and life of tool.

and it is required to find the speed at which the tool will last 120 minutes, other conditions remaining unaltered. Trace vertically above 40 minutes until the diagonal line, passing through the horizontal line of 110 ft. per minute, is reached. Follow this diagonal line until vertical over 120 minutes, when it intersects the horizontal line at 96 ft. per minute, which is the speed required.

CUTTING SPEED AND DIMENSIONS OF CUT (STEEL).

The value of the cutting speed varies with the dimensions of the depth of cut and traverse, shape and section of tool, as well as the material cut.

The cutting speeds for the various cuts and traverses given in fig. 62 correspond to a 2-hours' life of tool (which is considered to be the most economical life) when cutting a steel having an ultimate tensile stress of 38 tons per sq. in. and without any cooling medium.

The values were obtained when using a 1¼ in. square tool having a 60° plan angle, 70° cutting angle, and ⅛ in. nose radius.

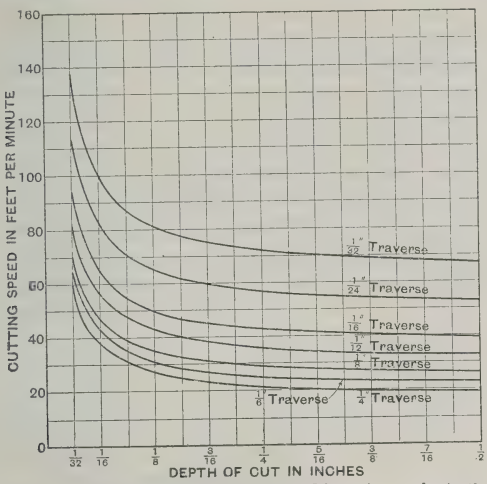

FIG. 62.—Relation between cutting speed in feet per minute (for a life of 2 hours) and depth of cut and traverse when cutting medium hard steel.

Cooling Medium.—When a liberal supply of cooling mediumi s used, the speed may be increased. For instance, with traverses of $\frac{1}{32}$ in. and ⅛ in. and various depths of cut on mild steel, it was found that the cutting speed might be increased by approximately 15 ft. per minute. The permissible increase will obviously depend upon the quality of cooling medium, dimensions of the cut, material cut, etc.

Tool Section.—Taking a 1¼-in. square tool as the standard, then for tools of smaller sections, say ½, ¾, and 1 in. square, the cutting speeds can be obtained by multiplying the value for the 1¼-in. square tool by the following factors: 0·815, 0·92, 0·97 for the sections in the order given, whilst for a 1½-in. square tool the permissible speed would only be about 2 per cent. greater than that of the 1¼-in. square tool.

Cutting Angle.—The results of the trials show that when the ratio of depth of cut to traverse is greater than unity, the 70° cutting angle tool gives the greatest durability for a given cutting speed, but when the ratio is equal to unity a cutting angle of about 80° is the most efficient and allows of an increase in the cutting speed of about 8 per cent. above that of the 70° tool. The relatively rough surface produced and the increased power consumption for the 80° cutting angle is likely to result in the 70° cutting angle being adopted for general workshop use. It may happen, however, that the power available is such as to demand a more acute cutting angle, in which case the permissible cutting speeds for tools having cutting angles of 50° and 60° are 71 per cent. and 82 per cent. respectively of that for the 70° angle tool, and these values are irrespective of the ratio of depth of cut to traverse.

Plan Angle.—Should the work and machine be sufficiently stiff or of a character such as would permit of a small plan angle tool, say 30° or 45° being used, then the cutting speed may respectively be taken as 1·55 or 1·21 times that given for the 60° plan angle tool. But should circumstances demand that a 75° or 90° plan angle tool be used then the permissible cutting speed is respectively 88 per cent. or 82 per cent. of that given for the 60° plan angle tool.

CUTTING SPEED AND DIMENSIONS OF CUT (CAST IRON).

The cutting speed when cutting soft cast iron, having a compressive strength of 29 tons per sq. in., with a 1¼ in. square tool, having a 75° cutting angle, ⅛ in. nose radius, and 60° plan angle (see fig. 59, p. 1071), are given in fig. 63. The speeds correspond to a 2-hours' life of tool (*i.e.* the length of time the tool will last before the cutting edge fails, and which is considered to give the most economical results) when cutting dry.

While the cutting speed decreases as the crushing strength of the material increases, a comparatively close relation between these cannot be given, as the cutting crumbles irregularly on the tool face.

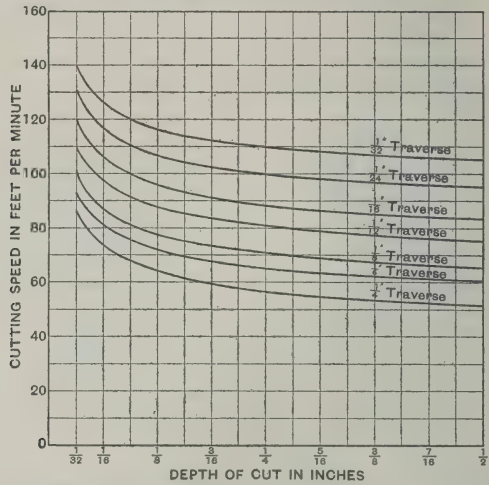

FIG. 63.—**Relation between cutting speed in feet per minute (for a life of tool of 2 hours) and depth of cut and traverse when cutting cast iron.**

The modification to be made in the cutting speed for other sections of tool, plan angle, etc., are for practical purposes similar to that given above for steel.

There is no close relation between the ultimate strength, or Brinell Hardness figure, of various metals and the cutting speed, but for ordinary straight steels (*i.e* containing little or no nickel, chromium, or tungsten), there is an approximation relationship which falls within ordinary workshop limits.

(*Proc. Manchester Assoc. of Engrs.* 1925.)

Cutting Lubricants.

The mineral oils best suited for use as cutting lubricants, either alone or mixed with animal or vegetable oil, are preferably of pale colour and low viscosity, ranging from 100 to 200 seconds Redwood at 100 deg. F., those of lower viscosity being used for high-speed conditions and those of higher viscosity for slow speeds. Tinged lard oil, containing as much as 10 or 15 per cent. of free fatty acids, is the animal oil most frequently used, either alone or in admixture : prime lard oil, which is almost free from acid, is more expensive, but is less inclined to gum under severe conditions of heavy cut and high speed. Wherever possible, a mixture of lard oil and low cold test mineral oil is to be preferred on account of greater fluidity in the cold. Cotton-seed oil oxidises more readily than rape oil, and should not be used for cutting lubricants that are to be employed in a circulation system.

Good cutting oils used straight will not cause rusting, but those containing fixed (animal or vegetable) oils, such as lard oil with a large percentage of free fatty acid, will give rise to verdigris on brass. Vegetable oils such as rape, with a small percentage of free acid, do not produce verdigris unless they are rancid. Cutting emulsions made up from cutting compounds or soluble oils and water cause rusting if they are used too weak or if they contain acid. Water containing sodium chloride is most destructive to emulsions and must not be used, nor must hard water on account of the precipitate caused by the calcium and magnesium salts in it. Emulsions of oil and water are not stable in the presence of even minute quantities of acid ; to a limited extent they can be reformed by neutralising the acids with ammonia, but excess of alkali may facilitate corrosion.

Factors in Selection.

Low speeds and shallow cuts require little cooling and lubrication. Low speeds and heavy cuts demand a lubricant of great oiliness, particularly if the material is tough. High speeds and shallow cuts demand a cutting medium with great cooling properties ; hence emulsions are

THE IRONMONGER

HARDWARE AND METAL TRADES ADVERTISER.

ESTABLISHED 1859.

PUBLISHED WEEKLY

28 ESSEX STREET, STRAND, LONDON, W.C.2.

For over seventy years The Ironmonger has been the leading newspaper published in the interests of buyers and users of hardware, metals and mill-furnishings.

To the factory owner and his buyer it is of equal interest, as in addition to voluminous information as to prices, etc., it publishes regularly reliable and informative articles on such subjects as :—

Losses in Belt Driving
Cutting Tools
Bolts and Rivets
Drills and Drill Grinding
Electric Furnaces
Heat Transmission
Boiler-House Efficiency and Economy

All this information is obtainable for the cost of a year's subscription, £1, which sum includes a copy of The Ironmonger Diary and Hardware Buyers Guide, published each December.

To anyone interested a specimen copy of The Ironmonger will be sent on application accompanied by trade card.

F. 1079

favoured and should be used if the speeds are particularly high. Turpentine substitute is a satisfactory lubricant for aluminium, but being inflammable must be used with care. A mixture of paraffin oil and lard or other cutting oil for high speed work on aluminium is also dangerous and has led to several fires. Cutting emulsions which possess the necessary cooling properties, and are not inflammable, are to be preferred. High speeds and heavy cuts demand a cutting lubricant with great cooling and lubricating properties; hence heavily compounded cutting lubricants of low viscosity must be used. For tough material and heavy cuts an emulsion containing 15 to 20 per cent. of a vegetable oil has been reported to be satisfactory.

Cutting emulsions are nearly always used for brittle material, and frequently for tough material if the speeds are high and the cuts light; when the material is tough and the cut heavy it is necessary to employ cutting lubricants used straight and containing 10 to 50 per cent. of animal or vegetable oils, or consisting entirely of such oils. Emulsions, in some cases, have been found to form a deposit on the working parts of automatic screw-cutting machines; this may be avoided by using straight oils, but emulsions should be adopted wherever possible in view of the present scarcity of oil. The amount of soluble oil or soluble compound used in preparing the cutting emulsion varies from 2½ to 20 per cent.; the richer mixtures are used for severe conditions, and the weaker for light duty or for materials like brass and aluminium, where there is no danger of rusting.

The cutting lubricant may be applied by hand by a drop-feed system, or by some system employing gravity or pumping. In large machine shops the cutting oil is sometimes circulated in pipes throughout the works, returning through other pipes to a central tank; group systems with central tanks are excellent where one mixture is used for all the machines on the circuit. The return pipes should be large and arranged for easy access for cleaning; isolating valves should be employed to sectionalise the system when large; efficient strainers should be fitted on all return pipes and pump sections, and should be cleaned daily. Tanks, as a rule, should be cleaned out every four weeks, and return pipes every four months. Any scum formed should be skimmed off the tanks daily. It must be remembered that the oil or emulsion, in any system in which it is circulated over and over again, is exposed to the admixture of dust and dirt from the machine shop and to the oxidising influence of air. The suction of any pumps that are employed should always be covered to prevent air from being drawn in, since aeration of the oil or emulsion has a strong oxidising effect upon it.

In machining aluminium (drilling, planing, etc.), use a lubricant of lard oil, kerosene, or a mixture of kerosene and gasolene or lard oil, for free cutting and a good finish.

Effects on Health.

Workers should be instructed not to wipe their hands on rags before washing, and to avoid washing their hands in the cutting compounds. Ether soap, which dissolves oil, has been found useful in preventing inflammation of the hair follicles, and dusting the arms with a powder containing equal parts of starch and zinc oxide before starting work prevents the action of the oil on the skin.

Workers whose hands have become the seat of septic infection should not be allowed to work on machines, as they are liable to infect the oil with germs and so infect others. As a general rule, frequent washing with soap and hot water is sufficient to bring about rapid cure of folliculitis produced by plugging of the glands. Subsequently the skin may be dusted with zinc oxide and starch powder, and where this has been insufficient a mild antiseptic applied on lint has relieved the irritation and given good results. Septic infection of the skin due to cuts should be treated on general principles with suitable antiseptic dressings.

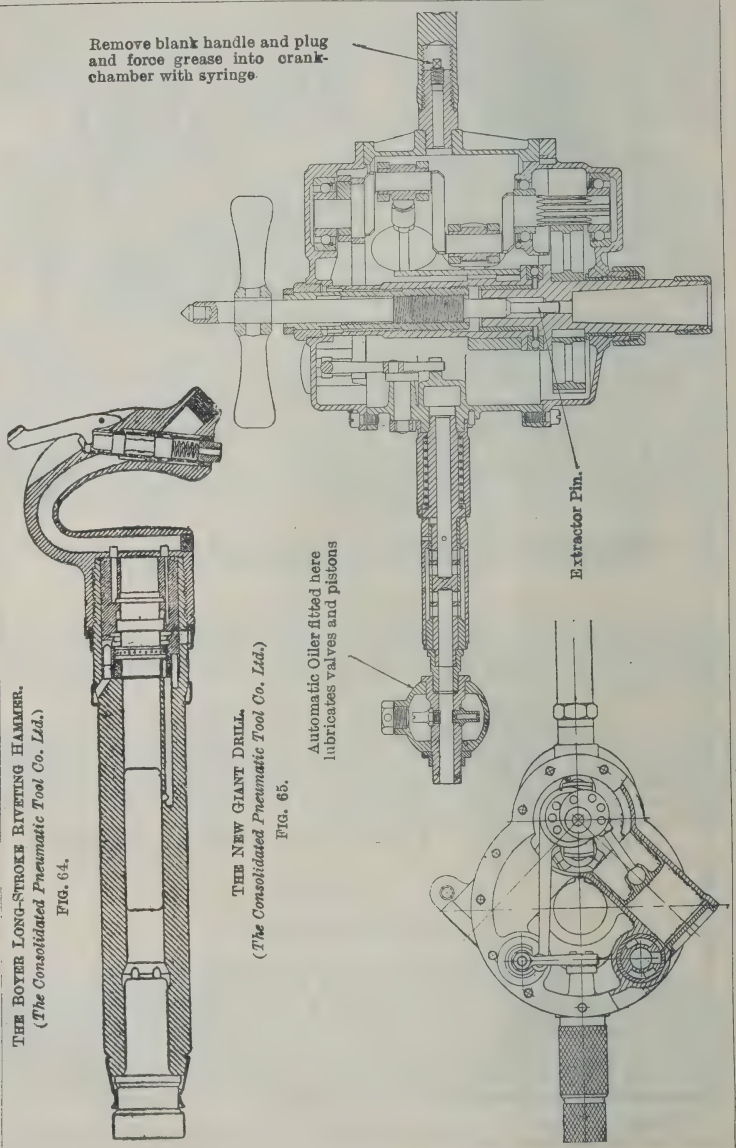
PORTABLE PNEUMATIC TOOLS.

The Boyer Long-Stroke Hammer.

(*The Consolidated Pneumatic Tool Co., Ltd.*)

This (fig. 64, p. 1080) is one of the best and most generally used of all pneumatic riveting hammers, at the present time. It has one distributing valve, which is placed at the rear end of the cylinder. The air-ports in the valve and cylinder of this hammer are so designed that the full air pressure is available to drive the piston forward on its working stroke, but the ports in valve and cylinder provided for effecting the return or idle stroke of the piston are of small area, so that the pressure used for this work is considerably reduced by wire-drawing, and the piston is returned practically without shock to the operator. The vibration of these hammers is thus reduced to a minimum.

For holding up against the riveting hammer, any of the present hand methods may be employed, and quite good work can be done either with the old-fashioned mawl, or a plain dolly bar



THE BOYER LONG-STROKE RIVETING HAMMER.

FIG. 65.

consisting of a piece of wrought iron weighing about 28 lbs. Where a suitable backing can be found for it, the pneumatic piston holder-on is most useful, and for boiler work and in certain classes of heavy shipyard riveting the hammer type of holder-on is frequently used. This gives a series of blows on the head of the rivet whilst it is being formed.

Pneumatic riveting hammers are now recognised as thoroughly practical and efficient tools for dealing with any class of work which was formerly done by hand, and rivets from $\frac{1}{2}$ in. up to $1\frac{1}{2}$ in. diameter can be closed by suitable tools. It takes from 7 to 10 seconds to close a $\frac{7}{8}$ in. snap-headed rivet.

The air consumption of these tools is generally from 28 to 35 cubic feet of free air per minute, and the pressure may be from 80 to 100 lbs. per square inch, the latter figure being necessary for the heaviest class of riveting, and particularly for steam- or water-tight work.

Caulking Hammers.

The chipping or caulking hammer has now taken its place as an indispensable every-day tool, without which present rates of output could not be maintained. The average chipping hammer will remove mild steel at the rate of $3\frac{1}{2}$ to 4 oz. per minute, and the air consumption is from 17 to 20 cubic feet of free air per minute: pressure from 80 to 100 lbs. per square inch.

Drills.

A pneumatic drill of average size can be relied upon to drill in mild steel plate 1 in. diameter holes at the rate of 1 in. to $1\frac{1}{2}$ in. deep per minute, and larger and smaller holes in proportion, the air consumption varying from 30 cubic feet in the average drills to 50–60 in the larger tools. Usual air pressure 80 lbs. per square inch. Reamering and tapping are also among the varied uses to which these tools can profitably be put. Pneumatic drills are now available in a large range of sizes, from a tool weighing 8 lbs. for drilling $\frac{3}{16}$ in. holes up to a weight of 85 lbs. and a capacity for 3 in. drilling and tapping. (See figs. 35, 36, 37, 38, pages 1044, 1045, 1046, and fig. 65, page 1080).

Pneumatic Tools for Salvage Work.

The chipping hammer and drill mentioned above can be fitted for use under water, for ship repairs, dock construction, and other similar work, and are already very largely used in this connection.

Air Mains and Receivers.

Air Mains for the distribution of compressed air are generally made of wrought-iron piping of steam quality, and should be so arranged that the rate of flow will not very much exceed 50 feet per second. At intervals along this main, or wherever tools are likely to be employed, a tee piece should be inserted which will take a connection for the flexible rubber hose which joins up to the tools. An important point to take care of is the provision of adequate means for draining any moisture from the air receiver or the pipe lines themselves, and it is advisable to arrange for the discharge of the compressor to deliver the air at the top of the receiver, and to connect the air main lower down. This assists in depositing any moisture which may be in the air as delivered from the compressor.

Air Receivers should be fitted with a manhole, in order that their interior condition may be examined from time to time, as it is possible for corrosion to take place, or on the other hand, if the lubrication of the compressor is not carefully attended to, a large deposit of oil will be formed, which may result in an explosive mixture being present in the receiver.

Air should not be throttled at connections. It is a good plan to introduce water traps in suitable places in a pipe system. Strainers should be carefully watched, they are liable to get choked; they may be cleaned by blowing air through them in the reverse direction.

Tubing and Tube Couplings.

To secure good, economical service, air hose must not kink. Kinking not only shuts off the supply of air at the time, but it creates a permanent injury in the wall of the hose, which later develops into a leak. To prevent accidents of this character, the thickness and number of plies must be proportioned to the size of the hose; the rubber must be of good quality; and the inner tube, fabric, and outer cover must be properly proportioned to each other.

Sometimes customers specify wire winding as a protection against outside wear. The practice is not recommended. It makes the hose heavy and hard to handle. Once bent, the hose is hard to reshape; and a wire covering is more costly than the thick rubber cover recommended as the best protection for the outside of the hose.

A moulded hose is advisable for any length over 50 ft. This type of hose eliminates extra couplings, which retard the flow of air and decreases the pressure at the tool. This is an important feature. It has been found that a 15-lb. increase in pressure can make a 37 per cent. difference in the amount of work accomplished by the tool.

The pressure which the hose will stand is inversely proportionate to its diameter. A 1-in. 6-ply hose may have a bursting pressure as high as 800 lbs., while a 2-in. 6-ply hose made of the same materials would burst at 650 lbs. Hence, care always should be taken to specify greater number of plies for the larger sizes.

Flexible Metallic Tubing (*The United Flexible Metallic Tubing Co. Ltd.*, 139 *Queen Victoria Street, London*) is being largely used for pneumatic tools. As the tubing withstands crushing and cannot kink, it is well adapted for conveying compressed air to pneumatic drillers and other machines.

TABLE GIVING THE THEORETICAL VOLUME OF EQUIVALENT FREE AIR, IN CUBIC FEET,

that will flow per minute at various pressures through straight pipes of different diameters, each 100 ft. long, without any reduction of pressure.

(The Consolidated Pneumatic Tool Co.)

Belliss & Morcom Pneumatic Hose Coupling.

(Belliss & Morcom, Ltd., Ledsam St. Works, Birmingham.)

This coupling (fig. 66), which is simple in construction and convenient in use, does not rely on springs to maintain its lock, being immediately sealed by the internal pressure, and cannot unlock of its own accord in or out of use. It is claimed to be absolutely air-tight; easily and quickly disconnected; practically unbreakable, being made from steel bar; dust-proof, and being gun-blacked, will not easily rust. Having no external projections, it can be easily drawn through close quarters or past work lying about the shop.

The rubber jointing, being held securely in place, cannot blow out, but can be easily removed by hand for replacement when required.

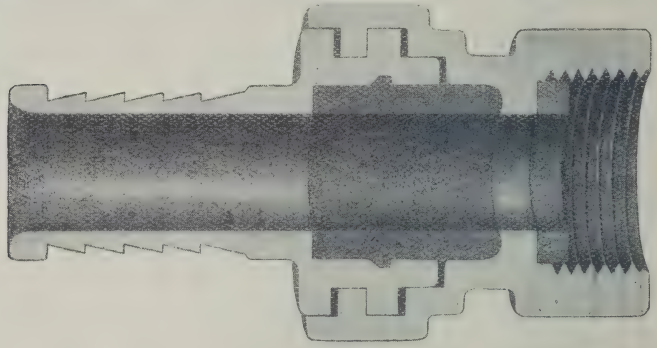

Fig. 66.

It is screwed on the shank and tapered to facilitate fitting on the hose. The ends of each hose pipe can be locked together, thus giving a neat appearance when coiled up. Additional hose for extensions can be connected up instantly. The coupling is supplied in the following sizes:—$\frac{1}{2}$ in. gas for chipping hammers, drills, riddles, etc.; $\frac{3}{4}$ in. gas for riveting hammers, etc.; 2 in. gas for coal-cutting tools and pressure mains.

The 'Flexstel' System of Ball and Socket Joints.

(W. H. Dorman & Co. Ltd., Stafford.)

This system of Flexible Pipe Joints provides complete units (fig. 67), having standard flanged or screwed ends, and may be readily interposed between suitable lengths of piping to provide for movements up to an included angle of about 40°.

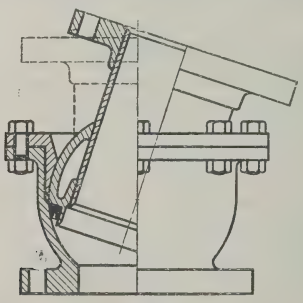

Fig. 67.

A special feature of the joint is the position of the packing ring, which is placed on a step on the leading end of the ball member, sealing the joint and insulating the spherical bearing surfaces

THE IRONMONGER

HARDWARE AND METAL TRADES ADVERTISER.

ESTABLISHED 1859.

PUBLISHED WEEKLY

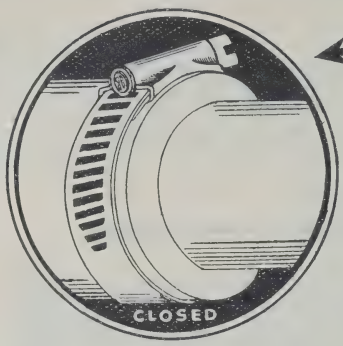
28 ESSEX STREET, STRAND, LONDON, W.C.2

For over seventy years The Ironmonger has been the leading newspaper published in the interests of buyers of hardware, metals and mill furnishings.

Its news service is invariably up-to-date and its information reliable, while its weekly record of current prices of staple commodities gives to its pages a world-wide reputation as a valuable buyers' guide for the purchasing departments of engineers, shipbuilders, collieries, etc. etc.

All this information is obtainable for the cost of a year's subscription, £1, which sum includes a copy of The Ironmonger Diary and Hardware Buyers Guide, published each December.

To anyone interested a specimen copy of The Ironmonger will be sent on application accompanied by trade card.



Tight with equal pressure all round.

THIS

'JUBILEE' Worm-Drive

(Pat.) **CLIP** British Manufacture.

Will always **stop the LEAK or DRIP,** and the type you should have fitted on your **RADIATOR JOINTS, UNIVERSAL JOINT COVERS, AIR, OIL and WATER HOSE JOINTS,** and all other purposes where clips or wire are required.

Finish now with your old-fashioned and inefficient types, **GET "JUBILEE" WORM-DRIVE CLIPS with GUARANTEED COMPLETE SATISFACTION.**

ALL IN ONE PIECE, NO PARTS TO LOSE

EASY-TO-FIT

NEVER LEAK

Manufacturers :

L. ROBINSON & CO.,

London Chambers, Gillingham, Kent.

Stocked by Factors & Merchants

F. 1085

from contact with the fluent. The outer surface of the packing is so shaped to conform to the spherical surface of the cup, and being rather full in size provides for initial compression and ensures the joint being leak proof at low pressures. The joint is effectively sealed at higher pressures by the lip formation of the packing ring.

These joints are made in a range of sizes from ¼ in. to 12 ins. in bore, sizes up to 3 ins. being usually made with ends screwed to British Standard pipe threads, and sizes 2 ins. upwards have flanged ends faced and drilled to suit British Standard Tables No. 1 or No. 2. Joints with screwed ends can be had with external or internal standard screw threads and are of many types, the straight joints having both single and double ball connections, while the range of elbow joints includes 90° single and double, 135° single, and 40° double.

'Flexstel' joints are used for conveying compressed air, steam, water, oil, gas, acids, etc., a suitable packing ring being fitted for each use.

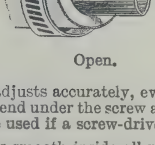
These joints can be fitted with obvious advantages to cater for the movement of machines or any moving bodies where it is desired to apply high or intermittent pressures of any of the fluents referred to above.

Jubilee Worm-Drive Hose Clips.

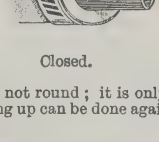
(Patent.)

(*L. Robinson & Co., Gillingham, Kent.*)

In these clips (fig. 68), a direct pull is exerted on a steel ribbon by a worm with heavy square-cut threads, which cannot be stripped. The arrangement gives an even and equal pressure round the hose, is easily fitted, and, when being removed, opens out automatically.



Open.



Closed.

Fig 68.

The clip adjusts accurately, even on hose too large or pipe not round; it is only necessary to push the free end under the screw and tighten up; the tightening up can be done again and again—a coin can be used if a screw-driver is not to hand.

The clip is smooth inside all round, and gives an even bearing; there are no sharp edges to cut, or spaces to permit leakage.

Being made of best quality steel, heavily galvanised, it is non-rustable and practically indestructible.

The whole arrangement is in one piece, so that there are no parts to lose and nothing to put together.

To fit from ⅝ in. to 3¼ in. outside diam., only five sizes are needed, viz.:—

Size.	Outside Diam. of Hose.	Size.	Outside Diam. of Hose.
No. 0	⅝ in. to ⅞ in.	No. 3	2 in. to 2⅝ in.
No. 1	⅞ in. to 1½ in.	No. 4	2⅝ in. to 3¼ in.
No. 2	1½ in. to 2⅛ in.		

Larger sizes are also supplied.

The clip will stand up to practically any pressure, and is officially approved by the British Air Ministry for use on aircraft; also by the Metropolitan Railway and the London, Midland & Scottish Railway for the automatic brakes on their trains, and by a number of fire brigades.

Care of Pneumatic Tools.

(1)

Unless pneumatic tools are kept clean, well lubricated, and limited to the uses for which they are intended, they will not give the service for which they are designed. Wherever possible, the air supply should be drawn from some point outside the building where the air is most apt to be clean, cool and dry. In any event, a strainer should be placed over the exposed end of the inlet pipe. Such a strainer can be easily made by covering the opening with wire netting over which one or two layers of muslin have been placed. A strainer should also be placed in the pipe lines leading directly to the pneumatic tools, and a strainer inserted between the pneumatic hammers and the hose nipple.

Lubrication.—Valves and pistons for both hammers and drills require a light machine oil, and as the compressed air which comes in direct contact with these parts has a tendency to drive the lubricant out through the exhaust, it is advisable to oil such parts freely and often, about once every hour while the tool is in constant use. Such portions of the tools as the gear and crank cases to which the compressed air does not have direct access are best lubricated with grease. This grease may be forced into the crank cases through the dead air handle by means of a squirt gun or syringe. A filling every 10 hours while the drills are in constant use gives the best results. It is a good plan to immerse pneumatic hammers in a bath of benzene or kerosene over-night and then blow them out under pressure the following morning, after which they should be thoroughly lubricated with a light machine oil.

(2)

The greatest damage done to the working parts of air tools may be found in the compressor, or rather in the air delivered by the compressor, for not by any means do all users of air tools appreciate the actual necessity for clean, dry air. Until the advent of the air filter, dirty, gritty, moist air had been the cause of thousands upon thousands of pounds being spent in needless repairs on air tools, and on the compressor itself, especially that of the portable type. Besides seeing that clean air is delivered by the compressor, care should also be taken to keep dirt out of the hose and leaders. Open hose ends are often allowed to lie on dusty, dirty, and even sand-covered floors, and then be hooked up to motors and guns without a thought of the necessity for blowing out before connecting.

Motor and gun valves require regular inspection in order that impending trouble may be caught in time, but with clean air and regular, systematic oiling with the right kind of oil, the time needed for inspection can be reduced greatly. Of course, the utilisation of a known, valued oil is a positive requirement. An oil of good quality will remain for some time in the valves and around the plunger of a riveting or a chipping gun, and guns with the right kind of oil have been known to work perfectly when oiled once in three hours of continual service.

(*'Compressed Air Magazine.'*)

Pneumatic Riveting.

According to information received from one of the leading East Coast shipyards, the best day's work on a shell with pneumatic riveting is 700 rivets of $\frac{7}{8}$ of an inch diameter, and for hand work, under the same conditions, 430. An average day's work, however, is considerably less than this, and may be taken as being 510 rivets with pneumatic rivets, against 264 with a hand squad, the figures being taken for work on all parts of one ship. According to the *Board of Trade Journal* the following may be taken as indicating the difference in the day's work of a hand and pneumatic riveting squad:—On the shell, with $\frac{7}{8}$ in. rivets, hand-riveting, 260 to 360 rivets; with pneumatic riveting, 500 to 550; on the deck, with $\frac{5}{8}$ in. rivets, hand-riveting 450, pneumatic 700; on deck with $\frac{3}{4}$ in. and $\frac{7}{8}$ in. rivets, hand-riveting 350, pneumatic 550. Again, the pneumatic tool requires fewer men to work it. A hand riveting squad consists of three men and one or two boys. From two of these squads three pneumatic riveting squads can be formed, effecting a saving of 50 per cent. in labour alone. A third advantage of the pneumatic tool is that it gives both the other great advantages with less exertion and consequently less fatigue on the part of the men. (*'Machinery.'*)

Cost of Compressing Air.

In a large shipyard on the north-east coast the actual cost of compressing 100,000 cu. ft. of free air to 100 lbs. per sq. in. pressure with electric current at 1*d.* per unit worked out as follows:—

	s.	*d.*
Power	20	1
Circulating water	0	3
Labour	6	0$\frac{3}{4}$

(*R. W. Wilson. Paper read before Inst. of Mech. Engs., Feb.* 8, 1924.)

Mechanical Hammers.

The Kango Electro-Mechanical Hammer.

In this hammer (fig. 69) an entirely new principle is employed, centrifugal force is utilised for converting rotary motion into progressive kinetic energy, 3,000 blows per minute being delivered at the head of the tool in use, whether cold chisel, fettling tool, keyway cutter, stone driller, stone dresser, etc.

In the upper part of the casing of the arrangement is a motor which drives through a sliding and flexible coupling a spline shaft operating the striking element, which is housed in the lower part of the casing, a special oil-retaining device being fitted to prevent the oil in the lower part of the casing reaching the motor.

The striking element consists of a special steel structure carrying a bevel pinion and two crown wheels. The pinion is centrally placed and drives the two crown wheels, which are mounted on pins projecting from the sides of the striker, in opposite directions. On one side of

each crown wheel is formed a heavy semi-circular weight, and the teeth are so engaged with those of the pinion that these weights are opposite each other when they are at the top and bottom of their revolution. The lower end of the striking element forms the hammer head, which conveys the blow to a specially formed transmitter secured in the lower end of the casing by a flexible diaphragm which renders oil-tight the lower part of the casing as the whole of the striking element works in a bath of oil. The striking element is kept towards the transmitter by a strong spiral spring which also serves to limit its oscillation.

The centrifugal force created by the weights on the crown wheels coming into juxtaposition at opposite points in their revolution, imparts a reciprocating motion to the whole striking element, the movement upwards being partially absorbed by the spring previously referred to, whilst the downward movement is free to convey the full impact to the transmitter and through this to the tool being used.

All tools can be instantly extracted or replaced.

Hammers are at present constructed suitable for 110, 200, or 220 volts; A.C. or D.C. current consumption about 300 watts only; the current supply can be taken from any lamp socket.

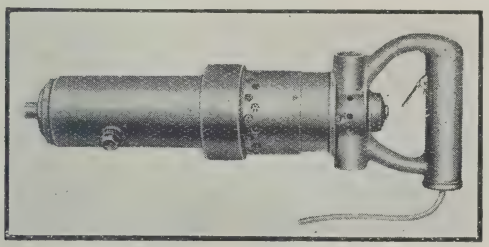


FIG. 69.

The weight complete of the hammer (which cannot be overloaded) is only 9 lbs.; no compressor is employed; all working parts of the striking mechanism work in an oil-bath and are easily accessible.

Diamond Turning Tools.

For turning materials, such as ebonite, galalith, bakelite, erinoid, and fibre, diamonds are greatly superior to any class of steel tool. More recently they have been applied to the turning of aluminium, aluminium alloys, and brass. On the Continent many of the largest makers of motor cars employ diamond turning for machining alloy pistons, and in this country the practice is gaining ground. On the Continent, also, diamonds are being used for boring gudgeon pin holes in aluminium pistons, and also as boring cutters held in bars for boring crankshaft bearing housings in aluminium crank-cases.

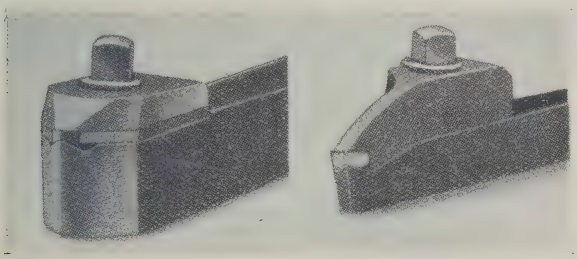

FIG. 70.

Fig. 70 shows two diamond tools specially designed for turning aluminium pistons. That on the left is for turning the cylindrical portions of the body of the piston, while that on the right is a square-nosed diamond for turning the piston ring grooves.

The diamond in the body turning tool is cut so as to give three small facets under 1 millimetre wide—a central facet and one on either side. When the tool is first used the central facet is set accurately so as to be parallel with the axis of the work.

With a feed of 0·1 millimetre the cuts taken by the diamond facet overlap, and providing the facet has been accurately set as described, the resulting finish is practically equivalent to a polished surface, free from tool marks. On an aluminium alloy piston, 3¼ ins. in diameter and 3½ ins. long, a spindle speed of 750 revolutions per minute is used, the best cutting speed being about 600 feet per minute, and the turning time about 60 seconds.

On such work each facet of the diamond lasts two months before any re-setting is required. As the remaining facets are still available, each diamond lasts about six months before it need be taken down and sent to the suppliers for re-cutting, after which it is useful for another long spell of work. It will be realised that with a very slow-wearing tool, such as a diamond, size is easily maintained, especially as little heat is developed during the cutting operation, the whole of the shaving being removed by a true cutting process without any sign of tearing.

A diamond tool appears to leave a finish greatly superior to grinding, and there is no risk of leaving abrasive particles embedded in the piston, it costs many hundreds per cent. more than a steel tool, but as its total life is about eighteen months, with very few resettings in the machine or redressings by the suppliers, it must be considered very economical, despite the apparently high first cost.

The diamond is of wedge shape, being deeper at the back than the front, while in plan the rear portion is dressed to V-form and fits a corresponding vee in the intermediate plate, seen under the upper clamp plate. The thickness of the intermediate plate is such that when the diamond is clamped in the holder the intermediate plate is gripped simultaneously, and the diamond relieved of any crushing pressure.

The diamond in the other tool is fitted without an intermediate plate, but is veed as shown on the under surface, to correspond with the lower portion of the holder. The diamond is the exact width of the slot required in the piston, but the extreme ends of the front cutting face are dressed to reduce the rake and remove the sharp corner. If these are left there is a risk of the diamond chipping at these points. These diamonds can be guaranteed to finish grooves in aluminium pistons within limits of 0·00025-in. in width.

The methods of holding these diamonds are the subjects of patents.

(' *Machinery*,' *August* 22, 1925.)

Files.

DESCRIPTION.

Single-cut.		*Double-cut.*		*Rasp.*	
Rough	Second-cut	Coarse	Smooth	Coarse	Second-cut
Coarse	Smooth	Bastard	Dead-smooth	Bastard	Smooth
Bastard		Second-cut			

The terms ' rough,' ' coarse,' ' bastard,' ' second-cut,' ' smooth,' and ' dead-smooth,' have reference only to the coarseness of the teeth, while the terms ' single-cut,' ' double-cut,' and ' rasp ' have special reference to the character of the teeth.

There are more than 50 types of files recognised in the file manufacturing trade, and each type is supplied in 24 different lengths. Each length can generally be obtained in one of five cuts of varying coarseness.

RE-SHARPENING FILES.

(1)

The sand-blast process consists of injecting fine sand against the backs of the teeth by means of a steam jet, and is applicable to all files, from the rasp to the finest Groubet files. The action of the sand is to cut away the backs of the file teeth, thus forming a straight level on the teeth back, and giving a new cutting edge, and the process occupies from 3 to 5 minutes.

(2)

Another method is first to carefully cleanse the files with hot water and soda; they are then brought into connection with the positive pole of a battery, in a bath composed of 40 parts sulphuric acid and 1,000 parts of water. The negative (zinc) pole of the battery is connected to a copper spiral surrounding the files but not touching them. This arrangement is the result of practical experience. When the files have been in the bath for 10 minutes they are taken out, washed, and dried, when the whole of the hollows will be found to have been attacked in a sensible manner; but should the effect not be sufficient, the files are replaced in the bath for the same period as before. Sometimes two operations are necessary, but seldom more. The files thus treated are to all appearance like new ones, and are good for 60 hours' work.

(3)

The following is a formula for an etching or recutting solution without electric current :—

Nordhausen (fuming) sulphuric acid	1 part.
Nitric acid	1 ,,
Concentrated sulphuric acid	½ ,,

All the above parts are given by volume.

The process is carried out by first submerging the files for cleansing for a period of 15 minutes in a solution of caustic soda in boiling water, the proportions being about 150 grains of caustic soda to 2 gallons of boiling water. With ordinary files this will suffice for about 150. After cleansing, the files are placed in a tank which is acid proof, and 13 parts by volume of water are added. The files should not overlap and should be arranged so that the liquor can obtain access to all parts to be recut.

The above mixture is then added and the files allowed to stand for 5 to 10 minutes.

To Clean Files.

Files clogged with tin or lead can be cleaned in a few seconds by strong nitric acid. For iron filings, use blue vitriol; rinse in water, and dip in nitric. For copper or brass, use nitric several times; for zinc, dilute sulphuric acid. After any of these treatments, rinse the files in water, brush vigorously, and dry in sawdust, or by burning alcohol on the file.

When files become clogged with aluminium or aluminium alloys a strong solution of potash will dissolve the aluminium and leave the file teeth unaffected.

Plating Files.

Chromium is used for the plating of files to be used for cutting soft metals. One firm which treats its files in this manner has found that the metal being filed does not clog up the file teeth as it does on untreated files; moreover, their useful life is greatly increased.

Auxiliary File Handle.

Figs. 71 and 72 show a form of auxiliary file handle, which was constructed for use in connection with an awkward filing job by Mr. H. Moore, of Hamilton, Ontario, and may be found convenient by other workers. The arrangement was devised to assist in filing out the ends of a number of channel pieces used on pump work. The position was such that only the tops of the fingers could rest on the file, and pressure could not be brought to bear on it in the usual way.

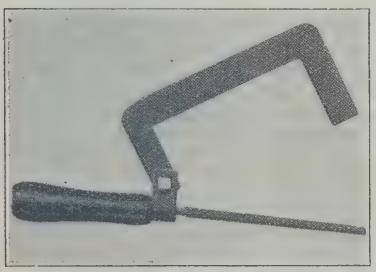

Fig. 71.

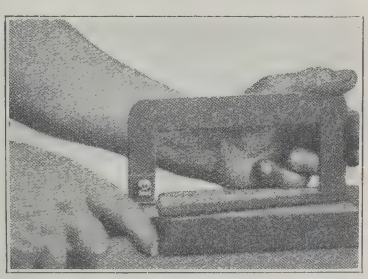

Fig. 72.

A clip of sheet metal was made to fit around the ferrule of the handle and a bridge piece, cut from No. 13 U.S. plate was pivoted to this on a bolt and nut. The bolt tightened the clip on the handle, and pressure could be brought to bear on the file tip by the bridge piece. As the bridge piece is jointed, any want of alignment between the file and handle can be accommodated. Fig. 71 shows the complete arrangement, and fig. 72 the auxiliary handle in use.

(*'The Engineer.'*)

Tube Cutters.

The particular feature in these cutters (fig. 73) consists in widely separated duplex rollers, arranged in a block on the spindle end, making it practically impossible to set the tube cutter

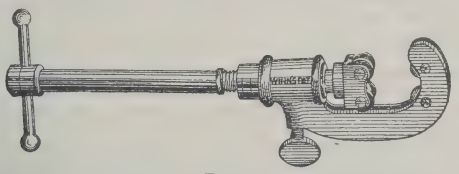

Fig. 73.

on the tube operated upon in any other way than absolutely at a right angle with it. All who have had occasion to cut a tube will realise the important gain this means, because no time is

lost in cutting screw tracks on the tube, and there is no consequent breakage of cutters. The rollers save all friction on the tube, and two cutters are provided in the hook, so that the tubes can be cut off with great ease and speed. There is a further saving of time by the use of these tools, in the quick adjustment for different sizes (¼ in. to 1½ in. for one tool).

Using Woodworking Tools on Metal.

Aluminium, Duralumin (in the annealed state or just after heat treatment), and soft brass, can all be planed with an ordinary carpenter's block or jack-plane, the same as wood.

The blade of the plane used for these materials will require more frequent sharpening, however, and it is better to grind it to a sharper angle, which gives less clearance and a larger included angle, thus making the blade stronger and better able to resist wear on the cutting edge. The ordinary wood chisel may also be used on the metals mentioned, provided it is ground with a shorter bevel. The ease with which these soft metals can be worked with hand tools is surprising. They can be sawn with a coping saw or compass saw.

Hack-Saws.

Insufficient attention is given to the lubrication of hack-saws while cutting. It is as necessary to apply ample lubricant to hack-saws as to any other cutting tool, and many power hack-saw blades merely rub their way through stock because the first few strokes have destroyed the hardness of the teeth, owing to the temperature attained in the absence of lubricant.

Hand hack-saw blades generally suffer the same careless treatment accorded to files. The proper use of these hand tools is not impressed upon the semi-skilled labour of to-day, and the hack-saw bills of many firms could be reduced considerably if more attention were given to this matter.

Experiments undertaken in France to determine the best method of sawing metal by hand indicate that it takes less time to saw off a rectangular bar of steel when the saw is moved parallel to the shorter side of the rectangle than when it moves parallel to the longer side. It was also found that the shorter the stroke of the saw, the quicker would the bar be sawed off. In sawing off a rail by a hack saw, it required nearly three times as long when the stroke was 4 ins. in length, as compared with when it was somewhat less than ½ in. in length. The work performed per minute decreases regularly for each ½-in. increase in the length of the stroke. It is also stated that by holding down the end of the saw farthest away from the workman—not by hand but by a weight—the time required for sawing through a bar is shortened, a thinner blade can be used, and a better surface on the ends of the sawed-off bar is obtained.

Cold Chisels.

A large number of the chisels now in use are not forged, shaped, and hardened in the best way to give long life and adequate service. Considering the making of a chisel from ⅝ in. octagon tool steel, the following method has been found to give good results:—

Forging.—Cut off a length of steel, depending on the length of chisel desired, and heat up the end for 2 ins. to a bright cherry-red. Trim off two opposite sides so as to form a blunt-nosed tool and eliminate the danger of lapping when drawing out. The horn of the anvil should be used in drawing out, inasmuch as this will have the least possible tendency to widen the piece, and therefore the minimum amount of 'edging-in' or hammering on the edge will be necessary. A chisel should not be hammered on the edge, because the grain of the steel will thereby be distorted or 'crumpled up,' and this always has a tendency to weaken any metal. If in the final forging operation the chisel gets a little too wide, it can be trimmed off on the emery-wheel during the grinding operation.

Draw the chisel out so that it will be about ¼ in. thick at the end and about ⅝ in. thick and 1½ in. back from the end. The forging should be finished with light blows until the steel has almost lost colour, but it absolutely must not be struck after the colour has disappeared. It is good practice to reheat the steel to a dull red without using any blast, and give it a second hammering with light blows until the colour has again almost disappeared.

The four important things to remember in forging a chisel are, therefore: Draw out at a good cherry-red heat: finish with light blows at a dull-red heat; do not hammer after the colour has disappeared; hammer as little as possible on the edge, and then only when the steel is fairly hot.

Grinding.—Grind the chisel before it is hardened, as it can be ground faster in this way without the danger of drawing the temper. The shape of the edge of the chisel is very important, although this fact is often overlooked. Fig. 74 shows a chisel ground with a concave edge. If this is driven down on to a flat surface, it is obvious that a great strain will be put on the corners, and they are almost sure to break off. Fig. 75 shows a chisel ground with a perfectly flat edge. If this chisel is driven down on to a flat surface and held perfectly straight the cutting strain will be distributed evenly over the entire edge, and the chisel will be satisfactory. It must be remembered, however, that it is almost impossible to hold a chisel absolutely straight, and,

therefore, either one corner or the other will be severely stressed by the chisel being tilted over. Fig. 76 shows a chisel ground with a slightly convex edge, which is by far the best for ordinary work. The corners of a chisel are always the danger point, and with the convex edge these corners are protected even when the chisel is tilted over considerably to one side or the other.

FIG. 74.

FIG. 75.

FIG. 76.

Hardening and Tempering.—After the chisel has been ground to the desired shape, heat it to a dull cherry-red colour for about 2½ ins. from the end, and quench it vertically in cold water to a depth of 1¼ ins., moving it up and down until no red colour is left in any part of the steel. The part which has been drawn out should now be polished with emery cloth and the temper drawn to a dark purple or a blue by holding the chisel over the fire or in a furnace. Always draw a chisel a little more in winter than in summer. It has been recommended to harden the chisel back much farther than usual, because a chisel so made can be ground a great many times without redressing. (*Joseph T. Byerson and Son, Chicago.*)

To Reduce the Internal Diameter of a Steel Bush.

A bush was required to be a force fit on a 6-in. shaft: and should have been bored 5·990 ins. ± 0·002 in., but was bored 0·015 too large.

The bush was heated to just a red, about 2 ins. up at one end, and just 1 in. of the 2 ins. dipped in cold water. It was next heated another inch or two up, keeping the first cooled inch as cool as possible, and then dipped a further inch into water. This was continued inch by inch, each cooled inch apparently pulling in the inch in the length adjacent to it until the whole of the bush (or sleeve) was pulled in quite twenty thousandths, and required to be skimmed out 0·005 in. to force it on to its shaft. (*J. T. T.*, '*Machinery.*')

Gripping Pieces of Uneven Width in the Machine Vice.

If two or more pieces have to be held in the machine vice for drilling or other operation, and their widths differ slightly, a strip of lead, *s*, placed as shown in fig. 77 will compensate for the

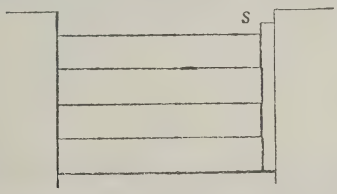

FIG. 77.

irregularity and afford a secure grip. Or a piece of belting, cloth, canvas, wire meshing, etc., will serve the purpose.

Block for Holding Tapered Work in the Vice.

Holding irregular or wedge-shaped parts in the vice while chipping, sawing, or performing other manual operations is awkward unless the parts are supported by blocking. It is possible,

however, to hold tapered work quite securely by using a simple block, such as shown at A in fig. 78, in conjunction with the regular vice jaws. This special block should be about the same

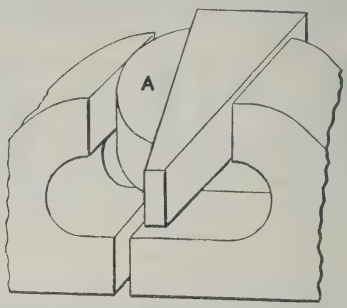

FIG. 78.

width as the jaws, the convex side being made semi-circular. It is preferable that the flat side of the block be checked or grooved in order to give it a better grip on the work.

(*G. A. L.*, '*Machinery*,' *June* 5, 1924.)

Pipe Bending.

Figs. 79 and 80 show two inexpensive methods in common use by practical men doing pipe bending work.

The first method, fig. 79, is to use a piece of hard wood with one end rounded, using a radius equal to half the width, then groove this rounded end to a depth equal to half the outside diameter

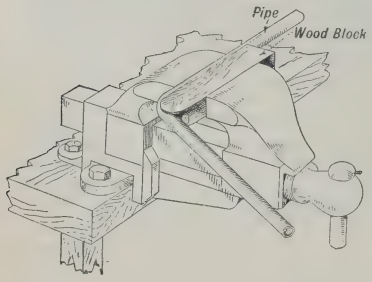

FIG. 79.

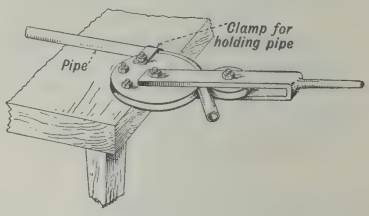

FIG. 80.

of the tubing. Clamp the block and the tubing in an ordinary bench vice as shown, and then pull the tubing around the block to make the desired bend.

In the second method, fig. 80, two iron grooved wheels of any desired radius are used ; the grooves on the outside diameter of the wheels should be made on a radius to fit the tubing to be bent. Mount these two wheels between two pieces of flat iron or wood fashioned at one end to form a handle. One wheel is attached to a bench as shown, or held in a vice.

Either of the two figures shows implements that do not cost much to make and are used extensively by practical men working tubing or pipe. Tubing or pipe bent this way does not require filling with sand, rosin, or any other material ; neither is it necessary to apply heat.

(*B. M. Adams*, '*Power*,' *January* 3, 1928.)

Plate-Bending Tool.

This tool is useful for the purpose of bending plates to a right angle. Fig. 81 shows a $\frac{5}{8}$-in. thick plate bent by means of the arrangement.

For the particular plate being bent, the tool consisted of a link, as shown in the figure, measuring inside about 15 ins. long and 2 ins. wide, and made of $1\frac{1}{2}$-in. diameter iron. It was laid across the anvil of a steam hammer, and the plate, heated at the middle, laid on top of the tool. A

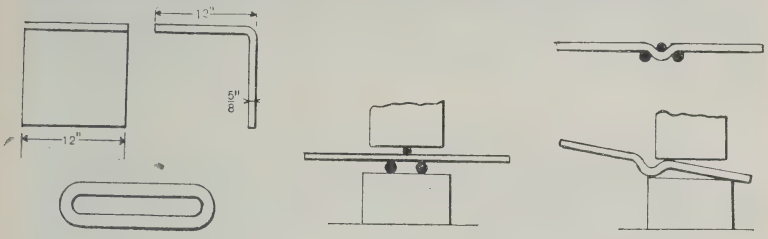

FIG. 81.

piece of $\frac{7}{8}$-ins. diameter iron, fully 12 ins. long, was laid across the top of the plate at the place where the bend was required, and directly above the inside space of the link underneath, as shown in section in the figure. One sharp blow of the steam hammer drove the piece of iron down and bent the plate; the plate then had three distinct bends. The tool was now removed and the two halves of the plate straightened, first one side and then the other, by a few blows, as shown in the figure, leaving a perfect right angle.

(*J. A.*, *Mechanical World*, *June* 15, 1928.)

Hand-Operated Tube Former.

The device shown in fig. 82 was recently made for use in forming a large number of small sheet-metal cylindrical tubes with lap joints. The tubes were for the purpose of inlet ventilators

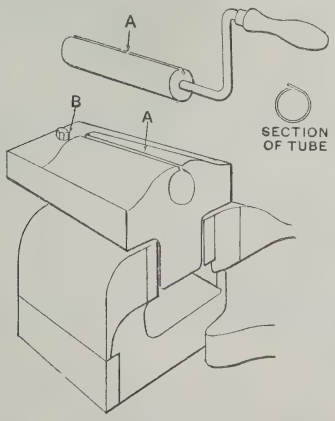

FIG. 82.

fixed in railroad passenger car floors, being used in connection with the steam heating apparatus. The stock used for the cylinders was No. 26 (0·0181-in. thick) lead-coated sheet steel, cut into pieces $2\frac{1}{4}$ by $4\frac{1}{4}$ ins.; the formed tubes being 3 ins. diameter by $4\frac{1}{4}$ ins. long.

The tube-forming device is clamped in a bench vice, and consists of a cast-iron body and a steel roller with a handle attached. The steel roller is $\frac{3}{8}$-in. in diamater, and has a narrow groove cut along one side, as shown at *A*. The metal part of the handle is oxy-acetylene welded to the roller and provided with an ordinary wooden handle. The stud *B* serves as a stop for locating the roller.

The operation of forming the sheet metal into a tube consists of placing the sheet in the narrow groove, holding it evenly in place with the left hand, and giving the handle a quick turn with the right hand; this forms the sheet metal around the tube, after which the roller is withdrawn and the tube slipped off. The tubes are formed with this simple device at the rate of from 600 to 700 pieces per hour. The lap joint is soldered, and a pressed washer is later secured to one end by soldering. The washer is used for securing the tube to the floor of the car with screws or nails.

(A.E., *Machinery*, *June* 28, 1928.)

Machining Aluminium.

In machining aluminium the tools should have more side and top rake than tools for cutting steel. The front clearance of the tool should be about 6°, the top rake from 30° to 50°, making the total angle of the cutting edge of the tool from 35° to 55°, and a side rake of from 10° to 20° aids the cutting action. The size of the angles used varies to some extent with the nature of the alloy and the work being done, the type of tool, and the conditions of use. It is very important to have keen tool edges, for on this factor the success of machining aluminium and its alloys largely depends. Hand stoning on a fine oil stone is recommended after a finish grinding in the preparation of edges.

Parting tools should have a top rake of from 12° to 20° and the front clearance angle should be decreased to about 3° or 4°. Milling cutters give the best results if they are of the coarse tooth spiral type and have a considerable amount of top rake on their cutting edges. Milling cutters with nicked teeth in some cases assist in decreasing the chip size. Face-milling cutters with inserted teeth, helical milling cutters and staggered tooth milling cutters can be made to work well with aluminium if the cutting edges are provided with suitable top rake. Also with considerable top and side rake good threads can be cut in aluminium of the softest quality in an engine lathe using a single-pointed threading tool. It has been found that very satisfactory taps for use in aluminium can be made by chasing threads on annealed high-carbon twist-drills followed by re-tempering and finishing.

Because of its lower modulus of elasticity aluminium has more recoverance than steel after a tapping operation, and the expedient of using slightly over-sized taps is therefore often resorted to in maintaining holes of required dimensions.

While the single-fluted twist drills used in drilling hard wood have been found in some cases to give better results than the usual form of drill, the best type for use with aluminium is that in which the flutes have a greater spiral angle, that is, more twists per inch; straight-fluted twist drills which are often used in drilling brass are quite unsuitable.

The most suitable saws for cutting aluminium are of the coarse tooth type, and hand hack-saw blades of the 'wavy-set' kind, work very satisfactorily.

Aluminium is machined to best advantage by using comparatively high speeds and fine to medium feeds. With ordinary carbon-steel tools speeds between 500 and 800 feet per minute are possible under some conditions and higher speeds are obtainable with high-speed steel tools. The feed may vary from $\frac{1}{4}$-inch for roughing cuts to a few thousandths for finishing cuts. Usually the finer the feed the higher the speed, and the more curl there is to the chip the slower the speed. When machining with coarse feeds it is necessary to remember that aluminium, like other metals, shows a rise in temperature and, moreover, its coefficient of expansion is greater than that of steel and, therefore, due dimensional allowances should be made.

A satisfactory lubricant or cutting compound for general use contains equal parts of kerosene and lard oil, while for heavy cuts and slow feeds, such as in roughing work or tapping, pure lard oil gives good results. In milling, sawing, and drilling, soluble cutting oils are satisfactory and more economical than kerosene and lard oil lubricant. Paraffin-base compounds such as those used in machining brass are quite unsatisfactory for use with aluminium. Alloys of the duralumin type, heat treated, possess the best machining properties, and aluminium-silicon alloys are the most difficult to machine.

(M.C., *Machinery*, Oct. 10, 1927.)

For grinding aluminium a soft or medium soft wheel should be used at speeds up to 10,000 feet per minute for carborundum wheels, and up to 6,000 feet per minute for wheels with shellac or other soft binders. Coarse wheels may be prevented from clogging by rubbing them with paraffin wax.

Single cut files should invariably be used for aluminium. Clogged files may be readily cleaned by dipping them in strong caustic soda solution, after which the metal particles are easily wiped off. This process should be followed by washing and drying in sawdust.

Machining Ebonite and Fibre.

Ebonite.

Ebonite should be run at the highest possible speed obtainable on the machine, and a mixture of 1 part of paraffin to 4 of lard oil used as coolant.

Turning tools, drills, reamers, and taps for ebonite should be of high-speed steel, glass hard, except where either diamond* or sapphire tools can be employed.

Drills should be ground away in the flute to allow of easy chip removal, and also to reduce the amount of surface of the tool in contact with the ebonite to a minimum. This principle of reducing contact to the lowest degree should be observed in all tools used on ebonite, since friction (together with the action of the sulphur) is a large factor in producing a temperature which quickly destroys the cutting edges.

Whenever possible, diamond tools* should be used for boring holes which are sufficiently large in diameter to admit a substantially mounted stone and possess a comparatively regular bore. For reaming, use plain flat reamers or bits, having two acute lips or cutting edges, and a land not exceeding $\frac{1}{64}$ in. in width or, as an alternative, a small bar with a bit or cutter of high-speed steel inserted in the end, this being simple and easily removed.

Tap and dies for ebonite should have narrow lands, and, wherever possible, should be run at a lower speed (if the machine is capable of it) than that employed for the rest of the operations on the component; 60 ft. per minute is a satisfactory speed, and there will be little danger of tearing-up the thread.

Feeds for turning, drilling, and reaming operations on ebonite should always be high, and about three times those used on brass. This remark does not apply so much to forming operations, when the feeds should be a little less than for brass on account of the fragile nature of the material.

Fibre.

Red and black fibre can be worked in much the same manner as ebonite as regards feeds, speeds, and the type of tools employed, but diamond tools are not so satisfactory as on ebonite on account of the irregular quality of these materials, for when the stone strikes a bad patch in the rod or tube there is a tendency to dislodge the diamond or sapphire. Drills, which should be of high-speed steel, should be fed at a higher rate than for ebonite, as should also reamers. The 1 to 4 solution of paraffin and lard oil will be found a good lubricant.

Erinoid, galalith, and other lactic base compounds are best machined when run at a high speed similar to that for ebonite, but, owing to the fact that these materials do not generate heat to the same degree as ebonite or fibre, they do not require any lubricant, and should be run dry. High-speed steel tools should be used, and wherever it is possible to employ a diamond tool* for either boring, turning, or forming, it will be found an advantage to do so. The same points in regard to the type of tools apply to erinoid and galalith as in the case of ebonite, whilst the feeds are approximately the same. (*'Machinery,' May* 24, 1923.)

Tool-Steel for Cutting Ebonite and Fibre.

High-speed steel frequently fails to give satisfactory results when machining ebonite and similar materials. Certain of the leading steel makers produce steels specially for work of this character. Edgar Allen & Co., Ltd., Sheffield, for example, make such a steel that requires to be quenched out from a temperature of 780° C., after which it is let down to a straw colour.

Saving Worn Parts by Electro-deposition.†

This process (developed at the Westinghouse Research Laboratory) has been used to build up shafts, pins, bolts, gear centres, and similar parts, and can be employed to build up the worn surfaces inside automobile engine cylinders, also for building up parts accidentally machined under size.

A plating bath is made up of 2·5 lbs. of commercial ferrous ammonium sulphate per gallon of water plus a small amount of ferrous carbonate (freshly precipitated and kept under water in order to keep the solution practically neutral) plus a small amount of powdered charcoal, which helps to prevent pitting. The equivalent amounts of commercial ferrous sulphate and ammonium sulphate may be substituted for the ferrous ammonium sulphate. If the solution is made up from the ferrous sulphate and ammonium sulphate, the granular or 'crystal meal' ferrous sulphate should be used. The ammonium sulphate must prove to be free from sulphocyanate when tested with ferric-sulphate or ferric-chloride.

All small pieces are plated in earthenware jars, and large pieces in lead-lined wooden tanks or stoneware tanks. Waterproof cement tanks can also be used. The anodes are made of

* See p. 1087.

† *Machinery*, Nov. 8, 1923 (*Abstract*).

'Armco' iron, cylindrical in shape. Micarta discs with a hole cut in the centre are fitted in each end of the anodes. The pieces to be plated are made the cathode and held stationary so that they extend into the plating solution through the holes in the micarta discs. The anodes are attached to a device which moves them up and down, thus keeping the plating solution stirred and the ferrous carbonate and charcoal in suspension. The temperature is held at approximately 60° C., a few degrees variation either way not doing any harm. A current density of 0·43 ampere per sq. in. is used. This deposits metal at a rate that increases the diameter 0·006 in. per hour.

This method of procedure applies only to pieces such as shafts, bolts, pins, etc. For pieces such as gear centres, automobile cylinders, etc., where the inside diameter needs to be reduced, the anode is made to go down through the centre, and micarta rings are fastened to the anode to obtain the required stirring. The current density could be raised considerably, but as the density specified adds the deposited material at the rate of 0·003 in. on a side, or increases the diameter at the rate of 0·006 in. per hour, it is evident that the ordinary repair job requiring an increase in diameter of approximately 0·010 in. to 0·020 in. can be quickly completed.

To clean the work, the piece to be plated is made the cathode in an alkaline solution consisting of 6 to 10 per cent. of caustic soda and 5 to 10 per cent. of commercial sodium carbonate, using a current density of 3 amperes per sq. in. for a period of three minutes. It is then washed in running water, transferred to a 30 per cent. commercial sulphuric acid solution, and given a high enough current density to make it passive for a period of three minutes or longer, according to the condition of the piece. If it is free from rust to begin with, three minutes is long enough, but if especially rusty it requires a longer time.

The piece being cleaned should come out of the acid cleaning solution bright and silvery, except in the case of cast iron, which will be black due to the graphite content. When taken from the acid cleaning solution, the piece is washed in running water and immediately transferred to the plating bath without giving it a chance to dry and form a thin film of rust. It is essential for the current density to be kept high enough (at least 3 amperes per sq. in.) in the acid solution so that the piece being cleaned is kept passive. When passive, there is a rapid evolution of gas, and the piece is bright and silvery in appearance when it is taken out, but if allowed to become active, it has a dull black appearance. When a piece is covered with oil or grease it is cleaned with petrol or benzol before being cleaned electrolytically.

If the method of cleaning and plating is properly followed, the deposited metal will be free from pits, bright and velvety in appearance, and will adhere perfectly to the parent metal.

As it is impossible to build up a piece accurately to size, it is necessary to build the work up a few thousandths over-size and then turn or grind it to the finish size. This method of recovery can be used with steel, cast iron, or case-hardened material, and the deposited material can be case-hardened when necessary.

If there are portions of the work that are not to be plated or built up, for protection these parts are coated with a mixture of 90 per cent. hydroline and 10 per cent. paraffin. The hydroline must have a high enough melting point so that it will not soften and run at 60° C. This protective coat is applied by melting the mixture and then dipping the piece to be coated, or by painting the mixture on with a brush. After the piece is plated, the protective coat can be readily removed by washing with benzol.

The following equipment would be required for a small plant: One 30-volt motor-generator set, 500 to 1,000 amperes capacity, according to capacity needed for cleaning; one 8 to 10-volt motor-generator set, 200 to 400 amperes capacity, or some other source of direct current such as storage batteries for plating; one or more ½-horse-power alternating-current motors for the stirring device; one or more reduction gears for the stirring device; and the necessary ammeters, voltmeters, crocks, heating coils, rheostats, switches, wire, tools, etc.

Metal Spraying.*

The unit of all the metal-spraying processes is the wire spraying pistol, a small and handy apparatus (weighing about 3½ lbs.), similar in appearance to a paint pistol, but differing in its operation and design. The wire (of the metal to be sprayed) (about 1 mm. in diameter) is pulled into the pistol and pushed through the nozzle (at a rate of about 12 ft. per min.) by means of rollers actuated by a small air turbine in the case. The pistol is fed with oxygen and some combustible gas under pressure, and also with compressed air, which projects minute particles of metal from the ever-melting end of the wire, the spray covering a surface about 2 ins. in diameter at a distance of 5 ins. from the nozzle.

The metal-spraying pistol will spray all metals (magnesium excepted) which can be obtained in wire form and which will fuse in the oxy-hydrogen flame.

* Abstract of paper on 'Metal Spraying and Sprayed Metal,' by T. Henry Turner and W. E. Ballard, read before the Institute of Metals, Sept. 1924.

For small articles, such as may be treated in rumbling barrels, a mechanical device has been introduced. Similarly, a machine is being operated which uniformly sprays with lead the outside of long metal pipes for use in the chemical industry. The interior of tubes may be sprayed by attaching to the ordinary pistol a long adapter, at the end of which a rotating nozzle is fixed. This produces a fan-shaped spray, and is driven by the air-blast used for projecting the metal. Thus, with the same unit, or pistol, tubes up to 12 ft. or so in length may be coated internally, so long as they are of sufficiently large bore to allow the introduction of the rotating end—that is to say, 1½ in. or more in internal diameter.

The preparatory sand-blasting of tubes internally presents some difficulty. The present-day practice is to sand-blast almost every article which is to be metal sprayed, and it is strongly advocated that where possible the article to be sprayed be heated. Devices are in use with which heating, sand-blasting, and spraying are carried out mechanically in one and the same machine, and the production of other such special machines is but a matter of time and of demand. For metal work sand-blast pressures of about 30 lbs. per sq. in. and hard black flint sands of about 20-mesh grade are recommended. After sand-blasting the surface should be sprayed at once, to avoid the possibility of contamination with grease and dirt.

Sprayed metal is being used successfully as a coating on ships' propellers. Composite coatings of more than one metal have given high resistance to corrosion. For example, zinc followed by aluminium is very suitable in cases of attack by atmospheres containing SO_2. It has been shown that the successful composite coatings are those of metals nearly related in the electro-chemical series. Very good results have been obtained by spraying zinc upon iron and steel objects—this has the advantage over practically all other methods of corrosion resistance, that it can be applied when and where desired over the top of rivets, cold-worked portions, and in general upon part or all of articles which are fully built up.

Building up Solid Articles by Spraying.

In a steel mould copper, zinc, tin, aluminium, and iron bars have been produced by spraying longitudinally for one set of tests, and transversely for a second set of tests. It was found that the bars so produced could all be sawn, filed, planed, turned, and machined much in the same way as solid metal. The bars had a clear metallic ring when struck.

Tested by scratch or by scleroscope, the sprayed metal is decidedly harder than similar metal when cast. However, when tested by the ball indentation method there seems little difference between the two, although the sprayed metal is in some cases slightly softer than the cast.

The oxygen consumption with hydrogen as the combustible gas (in cu. ft. per lb. of metal sprayed) is as follows:—lead, 2·64; tin, 2·86; zinc, 5·32; copper, 10·82; nickel, 14·6; iron, 17·4; aluminium, 22·7.

The approximate consumption of oxygen with other gases is given by multiplying the foregoing quantities by 1·7 for coal-gas, and 0·8 for acetylene.

The amount of 'metal (in lbs.) sprayed per hour,' using hydrogen, is as follows:—lead, 16·0; tin, 7·5; zinc, 5·5; aluminium, 1·5; copper, 1·25; bronze, 1·25; brass, 1·375. The metal 'deposited' is rather less than this.

The air pressure used in England is usually about 45 lbs. per sq. in., whereas on the Continent it is usual to employ a pressure of 35 lbs. The higher pressure used in England has been found to be an undoubted advantage when spraying lead, tin, and zinc, but it would be better if the air pressure were varied with the metals being sprayed. The higher pressure of 45 lbs. per sq. in. should be used with tin, and the lower pressure of 35 lbs. per sq. in. used when such metals as copper are sprayed.

The process is at the present time used in France and Germany to a considerable extent on shipping work, and for the protection of overhead transmission line poles and wireless masts for big stations. It is being increasingly used in this country for the protection of certain portions of ships and for propellers. Both wooden and steel bulkheads are being coated with zinc in many shipyards. It has also been used very successfully, in Germany, to replace the usual copper cable rail connectors on electric railways, so that at present on the Berlin and Hamburg underground railways there are miles of rail without a copper connector. During the war, when copper was scarce in Germany, the copper cables were removed from the electric railways in Berlin and electric connection between the two rails secured by sand-blasting *in situ* the rail ends and the inside surfaces of the fish-plates. These surfaces were then immediately sprayed with zinc, and when bolted together again gave excellent electrical contact, and apparently they have been satisfactory ever since. The electrical resistance of this type of joint has been found to be even less than with the best copper cable joints. It has become the practice of the Siemens-Schuckert works to install this type of joint in place of the customary one.

Hardness of Materials.

Different Methods of Determining Hardness.

The test to which a material is generally subjected in order to obtain a measure of its hardness may be of two classes, viz. :—

(1) The resistance offered by the material under investigation, (2) the resistance offered by the material to abrasion or cutting.

Of these, the first finds most extensive favour in practice, and the indenting medium may be a chisel, cone, or sphere. Repeated use on hard materials is inclined to blunt the chisel edge or point of the cone, and the sphere is the agent commonly adopted.

In 1900 Brinell introduced a method of ascertaining the hardness of a material by indenting it with a hardened steel sphere subjected to a predetermined load. The ratio of the load on the sphere to the area of indentation produced gives the hardness figure. The ball commonly used is 10 mm. diameter. The load for the softer materials is usually 500 kilograms, and that for the harder metals 3,000 kilograms.

The load should be applied for at least 30 seconds in order to secure equilibrium between it and the resistance of the material. The diameter of indentation is observed by means of a special microscope fitted with a scale, and from this the depth of indentation can be calculated since :—

$$\triangle = \tfrac{1}{2}\,(D - \sqrt{D^2 - d^2}),$$

where,

$\triangle$ = depth of indentation; d = diameter of indentation; D = diameter of sphere.

The hardness figure or number N for a load P is given by the expression:—

$$N = \frac{P}{\frac{\pi}{2} D \left(D - \sqrt{D^2 - d^2}\right)} = \frac{P}{\pi D \triangle}.$$

The hardness number is therefore inversely proportional to the diameter of ball and depth of indentation, and for a ball of constant diameter is directly proportional to the load. The hardness numbers for diameters of impressions made by a ball 10 mm. diameter under a load of 3,000 kilograms are given in the table, page 1223.

The depth of indentation may be obtained directly by means of a micrometer microscope by observing the difference between the readings of the datum line on the piston when the parts are brought together and after the load has been applied and removed. This procedure precludes the possibility of including the compression of the piston, sphere, and other parts of the machine beyond the datum line.

As it is difficult to bring the parts together without indenting the specimen to some extent, a small initial load may be applied. Observations of the datum line are then made when the initial load is applied, and also after the full load has been applied, and when the load has been brought back again to its initial value.

By measuring the actual depth of penetration, the error due to the elastic deformation of the sphere (which is included when the diameter is observed) is avoided. This elastic deformation is relatively greatest when the load, and consequently the indentation, is least. As the indentation increases so does the lateral component of the resisting force, and this tends to keep the sphere to its true form.

In testing some cast irons the metal flows from beneath the ball and causes a ridge to be formed which stands proud of the original surface, whilst with bronze and some of the copper alloys the metal is drawn in. In the case of the former the diameter observed is greater than the true value corresponding to the depth of indentation, whilst in the latter case the diameter is less than its true value.

The Shore Scleroscope.

This instrument consists of a small hammer, weighing about $\frac{1}{\sqrt{5}}$ of an ounce and fitted with a diamond which is somewhat spherical in shape at the striking end. The hammer is suspended on a stirrup piece fitted to a head on a vertical stand and upon which is also mounted a glass tube about 10 inches long and a graduated scale subdivided into 140 parts. The hammer is released and raised by a pneumatic device and moves within the tube. As the end of the glass tube is made to rest upon the material under investigation, the hammer always falls through a definite height and the measure of hardness is obtained by observing its rebound on the scale. The hammer on striking makes a permanent impression in the material, but as this is very small and irregular in outline it is impossible to measure the depth or diameter with any approach to accuracy.

Abrasion Test.

An early conception was to scratch a smooth surface of the material under investigation with a sharp point of a mineral, a number of minerals being selected to constitute a scale of hardness. In their order of hardness these were :—(1) talc, (2) gypsum, (3) calcite, (4) fluor, (5) apatite, (6) felspar, (7) quartz, (8) topaz, (9) sapphire, (10) diamond. The method is only suitable for materials which differ widely in hardness.

The Sclerometer.

This instrument was developed by Prof. Turner to obtain a measure of hardness of materials which differ but slightly in value. It consists of a diamond carried at one end of a balance lever in a horizontal plane and which rests upon a knife edge fitted into a vertical pillar. The pillar is free to turn by hand, so that the diamond is made to travel across the smooth face of the metal being investigated. The end of the lever carrying the diamond is loaded, and the weight in grams necessary to produce a scratch of standard depth gives a measure of the hardness.

With apparatus similar to the above, some have taken the width of the scratch produced by a diamond under a constant load as the measure of hardness. As the scratch is very minute, it has to be measured by means of a microscope, and the surface must be smooth and polished in order to give a sharp definition. The test is therefore more adaptable to the laboratory than to the workshop.

Drilling Test.

This test can be made with an ordinary sensitive drilling machine having a vertically free spindle. A constant load is applied to the spindle, so that the drill is made to penetrate the material under observation. The revolutions made in drilling a hole of predetermined depth gives a measure of the hardness or tenacity.

With the object of observing the variation in the hardness as the drill proceeds, the machine is fitted with a drum which rotates with the descent of the spindle. A screw, attached to the drum support, carries a nut in which is fixed a pencil. The screw is driven from the spindle, and as the nut cannot rotate the pencil moves in the plane parallel to the drum axis. The combined motion causes a diagonal line to be traced on a piece of paper around the drum, the height and horizontal length of the line being proportional to the depth drilled and revolutions respectively. The slope of the line varies with the hardness, and a soft or hard patch in the material under test is shown on the graph by the line becoming steeper or flatter in the order mentioned at that part. The drill is periodically tested for sharpness on a piece of material of standard hardness. (*Professor Dempster Smith.*)

BRINELL HARDNESS NUMBERS (for load (P) of 3,000 Kg.).

DIAMETER OF BALL (D) = 10 mm; $H = \frac{P}{D^2}\left(\frac{2/\pi}{1-\sqrt{1-(d/D)^2}}\right)$

3·2	364	4·45	183	5·7	107	6·95	68

For other test loads the hardness numbers are proportional to those in the table.

British Standard Tables of Brinell Hardness Numbers.*

(No. 240—1926.) ***(Abstract.)***

Definition.

1. The Brinell hardness number is the quotient of the applied load divided by the spherical area of the impression. The Brinell hardness number is given by the following formula :—

$$H = \frac{P}{\frac{\pi D}{2}\left(D - \sqrt{D^2 - d^2}\right)} = \left(\frac{P}{D^2}\right)\left(\frac{2\pi}{1 - \sqrt{1 - (d/D)^2}}\right)$$

where,

P = Load (in kilogrammes); d = Diameter of impression (in millimetres);
D = Diameter of ball (in millimetres); H = Brinell hardness number.

Note.—The spherical area must be calculated from the average diameter of the impression obtained by taking two readings at right angles, and not from the depth of the impression.

Apparatus.

2. (*a*) The micrometer microscope or other measuring device used shall be capable of measuring the diameter of the impression to $\pm$ 0·5 per cent.

Note.—An accuracy of measurement of $\pm$ 0·05 mm. (0·002 in.) may be accepted for impressions made with a ball of 10 mm. diameter.

(*b*) The balls used in Brinell hardness testing shall be of hardened steel or of some harder material.

Note.—When ordinary hardened commercial steel balls are used, Brinell hardness numbers exceeding 500 may be subject to error owing to permanent distortion of the ball. The error increases with increasing hardness of the material tested. With hardness numbers above 500 care should be taken to see that the balls are considerably harder than the material to be tested.

(*c*) The standard balls and loads used for Brinell hardness testing shall be as follows :—

Diameter of Ball.	Load.			
	$\frac{P}{D^2} = 1$	$\frac{P}{D^2} = 5$	$\frac{P}{D^2} = 10$	$\frac{P}{D^2} = 30$
mm.	Kg.	Kg.	Kg.	Kg.
1	1	5	10	30
2	4	20	40	120
5	25	125	250	750
10	100	500	1000	3000

The limit on the diameter of the balls shall be $\pm$ 0·0025 mm. (0·0001 in.).

Note —The same Brinell hardness number is given by tests on the same uniform material with balls of different diameters when the same value of the ratio $\frac{P}{D^2}$ is used.

Test Specimens.

3. (*a*) The centre of the impression shall be not less than two and a half times the diameter of the impression from any edge of the test specimen.

(*b*) The thickness of the test specimen shall be at least seven times the depth (t) of the impression as given by the formula $t = \frac{P}{\pi D H}$ or, alternatively, shall be such that no bulge or other marking showing the effect of the load appears on the side of the piece opposite the impression.

When tests are made on thin specimens, care should be taken to ensure that the under surface of the specimen is smooth and in good contact with a smooth supporting surface of hardened steel.

(*c*) The surface on which the impression is to be made shall be polished if the diameter of ball used is 1 mm. or 2 mm. If the diameter of ball used is 5 mm. or 10 mm., it is still advantageous to use a polished surface, but, if a high order of accuracy is not required, the surface may alternatively be filed, ground, or smoothly machined.

* By permission of the British Engineering Standards Association.

4. (*a*) The value of the ratio $\frac{P}{D^2}$ shall be as follows:—

For steel and materials of similar hardness	30
For copper alloys and materials of similar hardness	10
For copper	5
For lead and tin and materials of similar hardness	1

It is advisable that the ratio of the diameter of the impression to the diameter of the ball shall not exceed 0·6.

(*b*) The load shall be applied slowly and progressively to the test specimen.

(*c*) The full load shall be maintained for at least 15 seconds when the ratio $\frac{P}{D^2} = 30$ and for 30 seconds when the ratio $\frac{P}{D^2} = 10$, 5 or 1.

Note.—For steel, experiment has shown that an approximate indication of the tensile strength in tons per sq. in. can be obtained by multiplying the Brinell hardness numbers by 0·22. In cold-worked material and in exceptional cases the ratio may differ widely from this figure.

The Specification gives twelve tables with diameters (D) of balls varying from 10 mm. to 2 mm. and loads (P) varying from 1000 kg. to 4 kg.

Balls for Brinell Tests.

At a meeting (1927) of the American Society for Steel Treating, a paper was read on the use of an iron-carbon-vanadium alloy for balls for making Brinell tests. When Brinelling steels of such hardness as causes ordinary Brinell balls to deform, the alloy recommended for use in testing consists of 2·9 per cent. carbon and 13 per cent. vanadium, the remainder being iron. Balls made from this material, and heat-treated, are found, when tested on steels of approximately 700 Brinell hardness, to flatten only one-fifth as much as the ordinary balls used and only one-half as much as certain special balls.

The Herbert Pendulum Hardness Tester.

This instrument consists of an arched weight of 4 kg. pivoted on a fixed ball of 1 mm. diameter, the ball being of hardened steel, ruby, or diamond. The position of the centre of gravity of the instrument can be varied, but for all standard tests the centre of gravity is 0·1 mm. below the centre of the ball, and the instrument constitutes a very short compound pendulum. A curved spirit tube with bubble and scale graduated from 0 to 100 serves to measure the amplitude of the oscillations. On rocking the instrument the specimen is slightly indented, but the degree of hardness is not measured by the indentation but by the swing of the instrument; the readings are, therefore, expeditiously made.

Time Test.

This is the number of seconds taken by 10 single swings of the pendulum when placed gently on the specimen and caused to oscillate through a very small arc. The 'time hardness numbers' (seconds for 10 swings) vary from 3 seconds on lead to 20 seconds on mild steel, 85 on very hard steel, and 100 on glass.

The pendulum time test, like the Brinell test, measures 'indentation hardness' or resistance to indentation.

Work-hardening Test.

Another test is that which measures the 'work-hardening capacity' of metals, or the increase of hardness which can be induced in them by working them cold. In making this test the Pendulum is placed on the specimen in a tilted position with the bubble at 0 on the scale and is then released. The pendulum swings through a certain arc which depends upon the hardness of the metal, and the position of the bubble on the scale at the end of the first swing measures the 'work hardness' or resistance to working by rolling.

The next operation is to tilt the pendulum and complete the swing by hand. The bubble is then at 100 on the scale and is again released. The effect of tilting the pendulum is to elongate the impression and to harden the rolled surface by cold work. When the pendulum is released the ball rolls back along the hardened surface, and the position of the bubble on the scale at the end of the swing measures the hardness of the work-hardened surface. This process is repeated, the pendulum being tilted alternately to right and to left, and the hardness measured after each successive rolling by the ball until a maximum is reached. The difference between the first reading and the maximum reading measures the work-hardening capacity of the metal. Glass

has zero work-hardening capacity. The first reading and the subsequent readings are the same. Manganese steel is shown to be soft by the Brinell test, soft by the pendulum time test, soft by the first reading of the work-hardening test, but after being rolled by the ball it immediately becomes as hard as hardened tool steel, which explains why it cannot be worked.

The time test and the work-hardening test have important applications owing to the ease with which they can be applied to heated specimens. The pendulum equipped with a diamond ball measures the hardness of hot specimens as easily as cold, and the tests are conveniently made while the specimen is actually in the electric furnace.

GRINDING, ABRASIVES, AND POLISHING APPLIANCES.

ABRASIVE MATERIALS — NATURAL GRINDSTONES — ABRASIVE WHEELS AND BLOCKS — LUBRICATION — DRY VERSUS WET GRINDING — SELECTION OF WHEELS — SPEEDS OF WHEELS — MOUNTING ABRASIVE WHEELS — GRINDING MACHINES — WHEEL GUARDS — GRINDING PROCEDURE — CYLINDRICAL GRINDING — EXTERNAL GRINDING — CENTRELESS GRINDING — INTERNAL GRINDING — SURFACE GRINDING — GRINDING ALLOWANCES — POLISHING — SAND BLASTING.

Revised and amplified by Alfred B. Searle
(Consultant and Advisor on Abrasive Materials)

GRINDING, ABRASIVES, AND POLISHING APPLIANCES.

The appliances used for grinding and polishing may be divided into two chief groups :—

(*a*) The *abrasive materials*, which may be in the form of powders, liquids, wheels, blocks, cups, etc.

(*b*) The *machines* used in the application of such materials, and commonly known as ' Grinding and Polishing Machines.'

Abrasive Materials.*

The chief *natural* abrasive and polishing materials are sandstone, sand, emery, corundum, diamond dust, pumice, rotten stone, tripoli powder, rouge, lime, whiting, and chalk. The chief *artificial* abrasives are : (i) carbon silicide, which is known by various trade names, such as carborundum ; and (ii) fused or crystalline alumina or artificial corundum, which is also known under a variety of trade names.

These materials are ground and then sifted so as to ensure the particles being of sizes suitable to the particular purpose for which they are to be used ; this being a matter of great importance.

* For further details see *Abrasives*, by A. B. Searle (Pitman).

These abrasive materials may be used in the form of powders or pastes, or suspended in water, oil, or other convenient liquids (as liquid polishes), or they may be made into grindstones, wheels, blocks, etc.

Natural Grindstones.

Natural grindstones are made by cutting blocks of suitable stone to the desired size and shape. The stones used for this purpose are shown by the following tables :—

FOR GRINDING MACHINISTS' TOOLS.

Name of Stone.	Kind of Grit.	Texture of Stone.	Colour of Stone.
Nova Scotia	All kinds, from finest to coarsest	All kinds, from hardest to softest	Blue, or yellowish-grey
Bay Chaleur (New Brunswick)	Medium to finest	Soft and sharp	Uniformly light blue
Liverpool or Meling	Medium to fine	Soft, with sharp grit	Reddish
Yorkshire and Derbyshire grit stone	Medium to fine	Hard to soft, as selected	Biscuit to grey

FOR WOOD-WORKING TOOLS.

Name of Stone.	Kind of Grit.	Texture of Stone.	Colour of Stone.
Wickerolz	Medium to fine	Very soft	Greyish-yellow
Liverpool or Meling	Medium to fine	Soft, with sharp grit	Reddish
Bay Chaleur (New Brunswick)	Medium to finest	Soft and sharp	Uniformly light blue
Huron, Michigan	Fine	Soft and sharp	Uniformly light blue

FOR GRINDING BROAD SURFACES, AS SAWS OR IRON PLATES.

Name of Stone.	Kind of Grit.	Texture of Stone.	Colour of Stone.
Newcastle	Coarse to medium	Hard	Yellow
Independence	Coarse	Hard to medium	Greyish white
Massillon	Coarse	Hard to medium	Yellowish white

FOR PULPING WOOD IN PAPER MANUFACTURE.

Name of Stone.	Kind of Grit.	Texture of Stone.	Colour of Stone.
Grindleford Grit	Course	Medium	Biscuit

Maximum Speed of Natural Grindstones.

Except under expert advice, grindstones should not be run at a higher peripheral speed than 3,400 ft. per min. This corresponds to the following speeds of rotation :—

Diameter of Stone.	Revolutions per Minute.	Diameter of Stone.	Revolutions per Minute.	Diameter of Stone.	Revolutions per Minute.
Ft. Ins.		Ft. Ins.		Ft. Ins.	
8 0	135	6 0	180	4 0	270
7 6	144	5 6	196	3 6	308

To True Grindstones.

Drive at a moderate speed and true up with a piece of iron tube. Keep turning the tube, which should be held at right angles, and turn it as the edge grinds away. The stone should be *dry*, not wet.

Abrasive Wheels and Blocks.

The particles of abrasive material are held together by clay or by a mixture of materials in which clay is an important ingredient, the wheels being moulded from a plastic state and afterwards burned in kilns at a temperature of about 1,400° C. In other abrasive wheels the binding materials are shellac, rubber, or silicate of soda.

Abrasive wheels, blocks, etc., are classified according to the nature of the abrasive (corundum, carborundum, emery, etc.), the size of the abrasive particles and the hardness or tenacity of the bond.

Much economy, speed, and quality can be obtained by using abrasive wheels in the place of files, especially when the wheels are used on the varied machines to which they are applied. The great profit to be derived from the general introduction of abrasive wheels is due to saving in wages, files, increased output, and improved work.

It should no longer be assumed that a grinding wheel cannot remove metal and shape work as quickly as a steel tool, but the latter should be used when it can do the work more cheaply, and the grinding wheel when it excels. Poor wheels, or good wheels wrongly used, will still remove metal slowly, but a modern grinding wheel used in a modern machine is a milling cutter just as truly as if made of steel, and is to be regarded as a cutter with millions of teeth, which, while they may not cut so deeply, can cut more rapidly—as, for example, at speeds of 6,000 or more surface feet per minute. Cams and crankshafts can be produced more cheaply by grinding than by turning. With automatic grinders it is possible to turn out work even more rapidly. Where 300 pieces per day were ground by piecework, 2,300 are now produced.

The *grade* of a wheel is represented by a letter, being the hardest and the softest. The term 'grade' is confined to the relative hardness of the wheel or block as a whole, and does not refer to the hardness of the abrasive particles. This distinction is important, because the cutting or abrasive power depends quite as much on the bonding material as on the abrasive particles.

No wholly satisfactory method of grading abrasive wheels, etc., has yet been devised, various mechanical devices of testing having proved unsatisfactory. The method adopted by manufacturers consists in gouging the wheel with a tool resembling a screw-driver, the 'feel' indicating the grade with fair accuracy to an experienced tester. It is, however, almost impossible to compare accurately the grades of abrasive wheels made with different bonds, as they do not work equally satisfactorily with any material.

The term '*grit*' is used to indicate the sizes of the abrasive particles present, and it is usually expressed by figures indicating the number of meshes per linear inch in a sieve through which the abrasive particles will pass completely. Thus, in a 60-grit wheel or block the abrasive particles will pass completely through a sieve having 60 holes per linear inch. It should be observed that the grit only indicates the largest particles, and has no reference to their average diameter nor to the proportion of much smaller particles present. It is understood, however, that there is only a small proportion of particles sufficiently fine to pass through a sieve which is represented by the next grit figure.

Grit Sizes of Grinding Wheels.

Aluminium	,,	Elastic	24–46 Soft to Med. Crystolon
,,	Vitrified Wheel Co..	Elastic	24–46 Medium Carbolon

The *suitability* of an abrasive wheel or block for any given purpose depends on the grade or hardness of the wheel as a whole, on the grit or size of the abrasive particles, and on the *bond* which unites them together.

For grinding steels and the harder materials, *i.e.* materials with a high tensile strength, wheels or blocks composed of an aluminous abrasive (corundum emery) are preferable. For cast iron, chilled iron, brass, soft bronzes, aluminium, copper, granite, marble, leather, wood, and other materials of lower tensile strength, wheels or blocks composed of a carbide abrasive (carborundum, crystolon, etc.) should be used. The binding agent which unites the particles of abrasive also determines the suitability of the wheel or block for any given purpose. Thus—

(i) Rubber-bonded abrasives are very tough and resistant, and so are specially suitable where a bond of exceptional strength is required in conjunction with a thin wheel or ring, as in the case with various cutting operations, such as slotting iron plates, sawing stone, cutting glass and saw teeth, or sharpening milling cutters of awkward shape, as well as for cutting metals, grinding chilled iron rolls, and for other work where a fine finish is required. Shellac-bonded wheels are too soft for this purpose. They are also used where it is necessary that the shape of the abrasive article should be retained as long as possible. This is particularly the case with the thin cutting discs used by watchmakers, dentists, etc.

(ii) Shellac-bonded wheels are used for cutter and reamer grinding, pointing drills, sharpening knives, saws, and other edge tools, and for similar purposes as rubber-bonded wheels, but as they are more elastic they can be used to give a finer finish. They will not stand high temperatures, but can be used for wet or dry grinding. They are less porous and less free cutting than wheels with a vitrified bond. They are singularly free from ' glazing,' as the baked shellac has lost the stickiness characteristic of the natural material.

(iii) Silicate wheels are very close in texture, and as they cut freely they are very useful for grinding tools and cutlery.

(iv) Abrasive articles made with a vitrified bond are characterised by a high porosity, a great resistance to heat and acids, and great freedom in cutting. They may be used for almost any purpose if care is taken to select them of suitable grit and grade, though when very thin cutting wheels are required it is often preferable to use a shellac—or rubber-bond may be

preferable. If too much bond is present the abrasive articles tend to 'glaze' badly, owing to the bond not falling away with sufficient rapidity from the cutting points. With too little bond, on the contrary, the articles will be weak and, in the case of wheels, cylinders, or rotating rings, they may be dangerous on account of their liability to break when in use.

Lubrication.

The rate, effect, and efficiency of the grinding are also affected by the water or other lubricant applied to the wheel when in use. The function of the water is to carry away the heat resulting from the friction between the abrasive and the article being ground, and to wash away any loose particles dislodged by the grinding.

The water supply for all external grinding operations should be ample in volume without force. Using, say, a 14 in. diameter wheel, not less than 5 gallons and up to 10 gallons per minute should be used; on larger wheels 20 to 50 gallons per minute.

For many purposes, solutions of soap or emulsions of oil and water are preferable to plain water. A solution of carbonate of soda containing 2 oz. per gallon has the advantage of not producing rust, especially if ¼ or ½ pint of lard oil is mixed with it.

In grinding aluminium it is advisable to use a lubricant of lard, oil, kerosene, or a mixture of kerosene and gasolene or lard, or oil and gasolene.

Dry *versus* Wet Grinding.

In certain circumstances water may—or must—be dispensed with. Whenever it is necessary to see the edge of the wheel distinctly, to be sure of reaching some particular spot, water cannot be used, as it obstructs the view. Work revolving in the chuck or on the faceplate is also generally ground dry, as water is awkward to deal with on ordinary machines under such conditions. Cutters are also usually ground dry, although special care has to be taken to prevent 'drawing the temper' of the cutting edges. The amount to be removed is, in most cases, small, so that the sacrifice of time is balanced by the greater convenience of dry grinding.

More material can be ground away by dry internal grinding than by wet, and it is fairly common practice to run water on the work externally to dissipate as much heat as possible whilst grinding dry internally. On such classes of work as aeroplane cylinder grinding, or ring gauges, where a high degree of accuracy and finish is essential, water must be used, but it should be in such volume as to prevent as far as possible the chips being carried round to the wheel and interfering with the cut.

In *wet grinding*, care should be taken that the water supply is steady and adequate, and particular attention must be paid to this in the case of tool grinders, where it is of the utmost importance that the tool should be effectively covered with water, to obviate any loss of temper in the steel during the process of grinding. Some grinding machines provide for this; *e.g.* in one such patent machine the water is forced by a centrifugal pump through a series of small holes in the tool rest itself in such a manner as to completely envelop the tool being ground. A noticeable feature of this grinder is that there is total absence of splashing.

Selection of an Abrasive Wheel

In the the most important points to be kept in mind are *suitability for the particular class of work*, and *safety from accident*.

It is obvious to everyone that a wheel specially manufactured for fettling iron castings is not the one to be used for needle pointing, but few people, except those connected with the trade, have any conception of the number of kinds or classes into which such wheels have been divided and subdivided, each main group (designated by symbols, B, S, SS, G, R, M, etc.) being varied in hundreds of ways to suit the work.

The general practice is to state the purpose for which the wheels are required and leave the selection to the judgment of the makers; it is to their interest to give satisfaction. The other particulars to be given when ordering are—quantity required, diameter, thickness, and size of centre hole.

Grindstones are softer when wet than dry, and should not be left partly immersed in water, or they will wear unevenly. Stones made with sorel cement (basic magnesium chloride) as a bond should not be used for wet grinding as the cement is disintegrated by water.

Speed of Wheels.*

This varies somewhat according to the make and the purpose for which they are used, but no abrasive wheels should be operated at a speed exceeding that recommended by the manufacturer thereof. The following speeds are equivalent to a peripheral speed of 5,000 ft. per minute :—

SPEED TABLE.

Diam. of Wheel in Ins.	Speed. Revs. per Min.	Diam. of Wheel in Ins.	Speed. Revs. per Min.	Diam. of Wheel in Ins.	Speed. Revs. per Min.
1	19,099	18	1,061	42	455
2	9,549	20	955	44	434
3	6,366	22	868	46	415
4	4,775	24	796	48	397
5	3,820	26	733	50	383
6	3,183	28	683	52	369
7	2,728	30	637	54	354
8	2,387	32	596	56	341
10	1,910	34	561	58	330
12	1,592	36	531	60	319
14	1,364	38	503		
16	1,194	40	478		

The peripheral speed of a grinding wheel—which is a function of its diameter and the number of revolutions per minute which the wheel makes—has a marked effect on the apparent hardness of the wheel. Hence, the hardness or grade of an abrasive wheel or cylinder appears to vary with the speed at which it rotates. Thus, by running a soft wheel above its normal speed it appears to become harder, and by reducing the speed of a hard wheel it appears to become softer. Hence, by varying the speed within reasonable limits a wheel which is normally too soft or too hard may be used satisfactorily.

As a wheel wears, its peripheral speed is reduced and the wheel appears to soften, but by increasing the number of revolutions per minute so that the original peripheral speed is obtained the wheel appears to regain its former hardness. Many workers suppose that the faster the work revolves the greater will be the output, and so they use very hard wheels which require maximum driving power and cause a maximum wear of the machine. Yet, in most cases, they produce work of inferior quality which requires a longer time and greater effort to produce than if softer wheels and slower work speeds were used.

The following speeds are typical, but should be modified to suit particular cases :—

Application.	*Peripheral Speed in Feet per Min.*
Cylindrical grinding	5,500 to 6,500
Snagging and general off-hand grinding on bench and floor stands	5,000 ,, 6,000
Surface grinding	4,000 ,, 5,000
Knife grinding	2,000 ,, 3,000
Hemming cylinders	2,100 ,, 2,400
Tool grinding	3,000 ,, 4,000†
Vertical surface grinding machines	4,000 ,, 4,500
Elastic and rubber cut-off wheels	9,000 ,, 12,000
Polishing wheels	about 7,000

* Some of the following tables and recommendations are taken from a booklet issued by the National 'Safety First' Association, 119 Victoria Street, London, S.W. 1.

† Some large users of grinding wheels regard as maximum peripheral speeds for machinist's tools 0–1,000 ft. per min., and for carpenter's tools 550–600 ft. per min.

For speeds higher than the above, slightly softer grades should be used to off-set the harder cutting action ; for lower speeds slightly harder grades than would be ordinarily supplied should be used.

It is impossible to state exactly the speed at which any article or part to be ground should rotate. It is largely a matter of experiment, as the speed should be suited to the abrasive and to the nature of the material to be ground. With Norton cylindrical grinders a peripheral work-speed of 60 to 80 ft. per minute is often used for roughing, and 30 to 40 ft. per minute for finishing. It is customary to rough-grind at a higher surface speed of work than on finish-grinding.

In grinding cylinders the speed at which the article to be ground rotates is of great importance, as by running the grinding wheels at a constant speed and varying the speed of rotation of the article to be ground it is easy to secure uniform results from wheels having a variation in speed of 2,000 ft. per minute, and a variation from true grade within practical wheel-making limits. Thus, by varying the speed of the article to be ground, the necessity for variable revolutions for the wheel, or close limits of speed and grade for the wheel, are made unnecessary, and variable speed for the work accomplishes all that variable wheel spindles can accomplish, and much more, in a more simple way, at less expense.

The following grinding-wheel speeds are recommended for different types of grinding, in a recent number of *Grits and Grinds*, published by the Norton Co. of America :—

Type of Grinding.	Recommended peripheral speed (feet per minute).	Maximum peripheral speed (feet per minute).
Cylindrical grinding	5,500	6,500
Internal grinding	5,000	6,000
Snagging and general off-hand grinding on bench and floor stands	5,000	6,000
Surface grinding	4,000	5,000
Knife grinding	3,500	4,000
Hemming cylinders	2,100	2,400
Wet tool grinding	5,000	6,000
Cutlery grinding	4,000	5,000
Shellac and rubber cutting-off wheels	9,000	12,000

Every care must be taken to guard against the possibility of wheels being run at too high a speed. Thus, in the case of variable speed motor drive the speed control should be enclosed in a locked case, and cone pulleys should not be employed for speed regulation unless belt locking devices are provided.

New wheels should be run at working speed for 1 minute before applying the wheel to the work, the operator standing to one side. A heavy cut should not be taken with a cold wheel, but the wheel should be allowed to warm up slowly.

Storage of Wheels.

Extreme care should be exercised in the storage of wheels. They should be stored in a dry place and supported on edge in racks, except straight-sided shellac and rubber-bonded wheels of $\frac{1}{4}$ in. or less in thickness, which should be laid flat on a straight surface to prevent warping.

Wheels used for wet grinding should not be allowed to stand partly immersed in water, as this would tend to throw the wheel badly out of balance.

Mounting Abrasive Wheels.

If there is a large area of contact the method of mounting and safeguarding abrasive wheels and the condition of the grinding machine are of great importance.

Size of Spindle.

The minimum sizes of spindles in inches (at that part where the wheel is located) for the various diameters and thicknesses of grinding wheels should not be less than the following table :—

THICKNESS OF WHEEL IN INCHES.

Diam. of Wheel.	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
Ins.																			
6	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
7	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
8	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
9	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
10	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
12	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
14	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
16	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
18	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
20	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
24	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
26	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
30	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5
36	¼	⅜	½	⅝	¾	1	1¼	1½	1¾	2	2¼	2½	2¾	3	3¼	3½	4	4½	5

The spindle should be threaded left or right hand as required, so that the wheel clamping nuts will tend to tighten as the spindle revolves, and the threaded portion should be long enough to provide a bearing for the entire nuts when the wheel and flanges are in place.

The diameters of the spindle bearings for machines with overhanging wheels should not be less than the wheel-location diameters in the above table, and for single wheel machines (where the wheel is mounted between two bearings) should not be less than 80 per cent. of the diameters in the above table.

The wheels should be an easy fit on their spindles or locating spigots, and the soft metal bushing should not extend beyond the sides of the wheel.

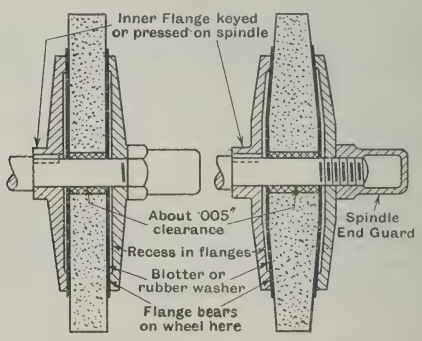

FIG. 1.

A grinding wheel should be fixed carefully and securely between recessed steel or iron plates or flanges about half the diameter of the wheel, with a washer of compressible material such as a sheet of thin rubber or one or two thicknesses of brown paper, on each side between the wheel and the flanges (fig. 1). These washers should be an easy fit on the spindle and not larger in diameter than the flange. If flanges with Babbit or lead facings are used, the thickness of the Babbit or lead should not exceed ⅛ in.

Spindle end-nuts should be tightened only sufficiently to hold the wheel firm, otherwise undue strain may be set up in the wheel.

Care should be taken in screwing up very thin wheels that too much force is not applied.

Flanges.

No abrasive wheel used on the periphery should be mounted except with suitable flanges. When wheel guards are fixed, straight, dovetail, or taper flanges should be employed. Where guards cannot be used, and also on swing frame and portable grinders, taper flanges should be used with taper wheels.

Flanges over 6 ins. diameter should be of steel of not less than 30 tons tensile. Smaller flanges may be made of cast iron. All flanges should be machined on the bearing surface and balanced. Every flange should be recessed at the centre at least $\frac{1}{16}$ in. on the side next to the wheel for a distance specified in the tables. The inner flanges should be keyed, shrunk, or pressed on to the spindle, and the bearing surface should run true with the spindle.

The minimum taper flange dimensions for taper wheels are given in the table, p. 1112. Such flanges should have a taper of $\frac{3}{4}$ in. per ft. No taper wheel over 24 ins. in diameter should be run with the wheel projecting from the flanges more than 4 ins. In the case of wheels 24 ins. diameter and under, the projection should not exceed 3 ins.

Dovetail flanges of the raised or countersunk type should be at least equal in diameter and thickness to the taper flanges. The taper provided for gripping the wheels should not be less than $\frac{1}{4}$ in. per ft. The recess should have ample clearance and be well radiused.

Cup, cylindrical, and sectional ring wheels should either be provided with guards or enclosed in protection chucks. Not more than a quarter of the height of the wheel should protrude beyond the guard or chuck. Where the thickness of the rim is less than 2 ins. the maximum distance that the wheel should project is 1 in. If the thickness of the rim is 2 ins. or more, a maximum projection of 2 ins. is allowable.

42	36	3	6	$1\frac{1}{4}$	$1\frac{3}{4}$	1	$1\frac{1}{4}$		
50	42	3	6	$1\frac{1}{2}$	2	$1\frac{1}{4}$	$1\frac{1}{2}$		

Both flanges should be of equal diameter, to avoid cross-straining of the wheel. The inner flange should be keyed to the shaft and abutting against a shoulder on the same. Various firms have special mountings which have proved satisfactory.

Wheel Guards.

All abrasive wheels should have a guard or protection hood made of rolled steel. The hood should cover as much of the wheel as possible and also the spindle rod. The hood should be constructed to act as a dust hood which, when connected with an exhaust system, will eliminate the injurious effects of wheel dust.

To meet the requirements of factory inspectors, a number of wheel guards, good, bad, and indifferent, have been introduced by manufacturers. The features to be looked for in an appliance of this kind are:

(1) That it is of ample strength; (2) that it can be readily adjusted to follow the wear of the wheel. (3) The maximum angular exposure for guards used on bench and floor grinders should not exceed 90°, the exposure beginning at a point not more than 65° above the horizontal plane of the wheel-spindle. When the work demands contact with the wheel below the horizontal plane of the spindle the exposure should begin not more than 65° above, and extend not more than 60° below, the horizontal spindle plane. (4) On cylindrical grinders the maximum wheel exposure should not exceed 180°, beginning at a point not more than 65° above the horizontal spindle plane. (5) The maximum wheel exposure on surface grinders should not exceed 150°, and on swing frame and portable grinders 180°, the top half of the wheel being protected at all times. (6) Guards should be so constructed that the peripheral member may be adjusted to preserve the maximum wheel exposure. The distance between the wheel and the peripheral member should not exceed $\frac{1}{4}$ in. The connection between the peripheral and side members or between the parts of a section guard should have a strength in a radial direction at least equal to the strength of the material of which the guards are constructed.

It is essential that the guard should be kept close to the periphery of the wheel in order to limit the flight of any portion which may break away.

Face or Cup Wheels ought to be protected by being well and properly secured inside a Safety Adjustable Chuck, designed to allow only a small portion of the wheel to project whilst at work, and constructed so as to secure and support the wheel as close to the grinding face as possible.

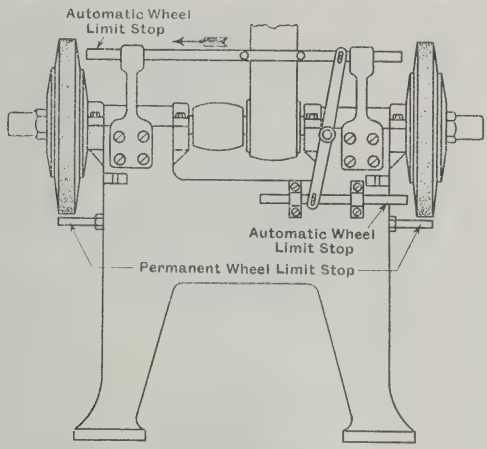

FIG. 2.

Machines fitted with two or more speeds should be provided with safety devices to prevent the maximum speed of the wheel being exceeded. In fig. 2 is shown a two-speed machine fitted with stops to limit the diameter and to prevent the belt being shifted to the high-speed pulley when the wheel exceeds a predetermined diameter.

Wheel Dressers.

Before using, the wheels should be trued up on their own spindles with a truing tool, and they should also be turned up when they get out of truth through wear.

Wheel dressers are used for 'truing' worn wheels; they should be equipped with rigid guards of sheet or cast metal over the tops of the cutters, to prevent flying pieces of broken cutters or wheel-particles from injuring the operator.

Dust Collection.

Dust generated by grinding should be suppressed or removed; preferably by localised exhaust ventilation. The hoods may be combined with the wheel guards or quite separate. They should be adjustable and should enclose the wheels as far as practicable. Hoods and ducts should be of substantial construction.

Except for very light dusts a pressure type of fan is a necessity, and special attention should be given to (*a*) the fan capacity; (*b*) the correct proportions and shapes of the ducts and branches; and (*c*) the means of collecting the dust after it has passed the fan. The efficiency of an exhaust installation is greatly increased by separating by gravity the heavy dust, burrs, fins, and miscellaneous material from the light dust, so that only the latter is directly dealt with by the fan. For this purpose some form of dust-separator (usually a cone) should be inserted in the duct between the hoods and the fan.

Rests.

Grinding wheels should revolve towards the rests, and the rests should be moved close to the wheels so as to prevent work being jammed between the rest and the wheel. The rest must never be moved while the wheel is in motion.

GRINDING MACHINES.

The modern grinding machine is practically a finishing machine in which the work produced needs no further correction. The sliding surfaces of the machine must be perfectly true planes, and there must not be rigidity, particularly in the grinding-wheel head. It must be heavy enough

to carry the largest and broadest wheels with which the machine may be possibly fitted, and also to overcome any possible want of balance in the wheel itself. The spindle and its bearings should be of ample proportions. The machine should be easily operated and controlled in its movements, so that a maximum amount of work can be obtained from it.

It is imperative that grinding machines be specially designed for the purpose intended, made of the best quality and workmanship, and that great care be taken in securing a suitable foundation as free from jar and shake as possible. The stands or bodies of the machines ought to be of a sufficient strength and massiveness to correspond with the size of wheel used. The same remark applies to the spindle, which must run in long and accurately bored bearings.

If the spindle is loose and cannot be put in good condition, a harder grade of wheel must be used than would ordinarily be recommended, so as to overcome the tendency to pound the wheel face to pieces. Light, flimsy machines, and those improperly secured to the foundation, also require harder grades than would ordinarily be used. Machines are frequently placed in the middle of a wooden floor which vibrates badly, and in this case harder wheels must be used than for a machine on a firm, solid foundation. A machine which is too light or imperfectly made is always a nuisance and is liable to prove very expensive. It is only too easy for good work to be spoiled by such machines, and they add unnecessarily to the cost of grinding, because they cannot be driven at the most appropriate speed for the work and because of various 'dodges' which must be used to obtain satisfactory results.

Rotary abrasive appliances may be mounted in a fixed frame—in which case the article to b ground, cut, or polished is moved gradually forward—or the work may be fixed and the abrasive mounted on a moving frame, so that it travels both forward and from side to side. There is an increasing feeling that this principle is wrong even in light machines ; it is impracticable in heavy ones, where a wheel-head may weigh between 1 and 2 tons. When a heavy wheel is grinding to within $\frac{3}{1000}$th part of an inch, revolving at a speed of 6,000 ft. per minute at the surface, and operating across a cutting face from 2 ins. to 4 ins. wide, it is clearly not a good mechanical proceeding to traverse such a mass under such conditions. The present practice, therefore, is to put plenty of mass into the wheel-head and to support it rigidly directly from the floor. Then the only movement which it receives is that of feeding inwards to the work. Incidentally, also, the necessary travel of the table requires a long table, which, again, avoids excessive wear. A slow table or traverse speed should be used when taking heavy cuts, but for finishing a high traverse speed is preferable.

The belt-drives from cumbrous overhead shafts have disappeared from all except the smaller and medium-sized machines, as electric drives have largely displaced this clumsy method and permit overhead-travelling cranes, or overhead tracks, to have free range. The large cylindrical grinding machines of to-day, therefore, have no belt-drive from above. A motor is installed somewhere alongside the bed, and the grinding wheel is belt-driven from that ; the work speeds and the wheel-feeds are arranged through gears enclosed in boxes protected from grit. The convenience of this arrangement, which is only rendered possible by the electric drive, is inducing manufacturers to adopt similar arrangements for the smaller machines.

In the best machines no mild steel and cast iron is used for shafts and gears. High carbon or alloy steels alone are used for these. Nickel, nickel-chrome, or chrome-vanadium steels ensure strength and durability, without which the small shafts and gears of the pitches would soon show serious wear. Friction is reduced by the universal fitting of ball-bearings for taking circular and end thrust. Lubrication is provided in various ways, ring-oiling to the main bearings, forced water-supply to the work and the wheel, and a large supply-tank or tanks with a circulating pump. New forms of steadies have been evolved, and more are used, besides which steadies for some duties are specially designed. The necessity for supporting work almost continuously receives more recognition than it formerly did, and the work is better supported on the bottom and in opposition to the wheel.

As good grinding machines are costly, concessions to the requirements of the smaller firms, in the form of various attachments, are inevitable, but the tendency is towards using plain grinding machines, each limited to one set of functions, every detail being considered and worked out for that duty alone.

Van Dorn Tool Post Grinder.

This machine, fig. 3 (made by the Van Dorn & Dutton Co., Cleveland, Ohio), is furnished with an internal attachment as shown. It may be used for internal and external grinding on the lathe, tool grinding on the milling machine, and surface grinding on the shaper or planer. The spindle makes 4,500 revolutions per minute, and the weight of the machine is about 24 lbs. These machines are extremely useful on a wide variety of work in all engineering shops.

All parts of these machines are made accurately to gauge, ensuring perfect interchangeability. All adjustments may be easily made without removing any part of the machine. The taper bearing at the wheel end ensures the correct bearing adjustment being maintained. The bearing for taking the end thrust may be adjusted to exceptionally fine limits. The bearings are bronze and the lubricating system is very efficient. The motor is air cooled. The armature is form wound, a commutator of special design giving great rigidity and perfect insulation. The windings are insulated by a special process. The brushes are easily accessible. Adjustable rear handles are on hand types.

Bearings.—The design of the bearings is a special feature of Van Dorn grinders. The bearing for the wheel end is so constructed that adjustment for compressing the bearing can be effected

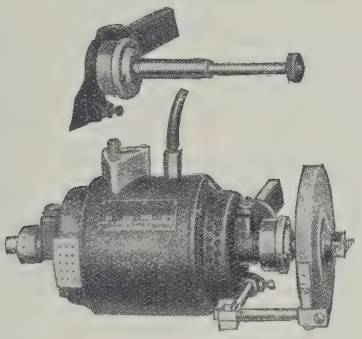

FIG. 3.

in addition to expanding; thus a perfect running fit can be obtained, whilst efficient locking arrangements ensure that the adjustment cannot be disturbed.

Longitudinal adjustment is accomplished by means of a double thrust bearing provided with a dial cap. By depressing a locking pin the dial may be moved in either direction, enabling the adjustment to be made within very fine limits.

PORTABLE PRECISION GRINDERS.

This grinder, fig. 4 (*The Consolidated Pneumatic Tool Co., Ltd.*), is specially adapted for fettling castings and grinding out cylinders; for this latter purpose it is fitted with a shaft

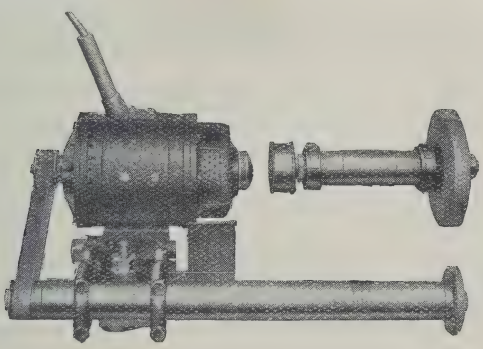

FIG. 4.

extension. The arrangement consists of a high-speed motor mounted in a special arbor, and belted to a shaft which carries an emery wheel. Two or more replaceable shafts are provided, one taking a large, and the other a very small wheel, so that a wide variety of grinding work, from motor cranks and cylinders to valves, jigs, and small tools, can be done.

Grinding Procedure.*

Cylindrical Grinding—External.

The best average *surface speed* of modern grinding wheels, as made to-day from artificial abrasives, is about 6,000 ft. per minute for external cylindrical grinding, and the useful speed range is from 6,500 to 5,500 ft. per minute; below this speed excessive wheel wear is liable and very probable, and grinding machines should be arranged so that the effective life of the wheel falls within this range. It is of the utmost importance that the speed of the wheel be maintained during the cutting operation, no matter what the speed may be, and the drive should be sufficiently powerful to prevent slowing down during momentary heavy cutting. Not only is the wheel wasted by being allowed to slow down, but the wheel face is destroyed and more frequent truing up is necessary. It is more economical, from the point of view of wheel wear to metal removed, to keep the speed up so that softer and freer cutting wheels can be used, the speed enabling them to stand up to heavy cutting without undue wear, and, further, such wheels have very little tendency to glazing.

The *grade* of the wheel is determined by the material to be ground and the rigidity or otherwise of the work, and whether it is of large or small diameter. No definite rule can be laid down for the adoption of any particular grade, but it is unusual in general machine work to require more than two wheels to a machine, one to grind all classes of steel work and the other to deal with all cast metals. Closer grading can be done where the work is all of one class, as, for instance, a machine may be employed wholly on cast-iron pistons, crankshafts, or piston-rods, etc., in which cases particular grades of wheels can be employed.

The *diameter* of the wheels should be as large as possible.

The direct result of using large diameter wheels is economy of operation, the cost of wheel per cubic inch of material removed being less than in the case of the smaller wheel.

The *wheel width* has a direct result on the output, providing it is made use of, and to utilise a wide wheel to its full extent the table-travel must correspond.

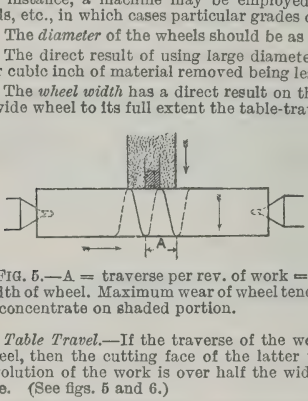

FIG. 5.—A = traverse per rev. of work = $\frac{3}{4}$ width of wheel. Maximum wear of wheel tends to concentrate on shaded portion.

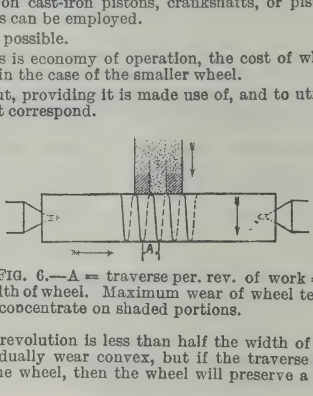

FIG. 6.—A = traverse per. rev. of work = $\frac{1}{4}$ width of wheel. Maximum wear of wheel tends to concentrate on shaded portions.

Table Travel.—If the traverse of the work per revolution is less than half the width of the wheel, then the cutting face of the latter will gradually wear convex, but if the traverse per revolution of the work is over half the width of the wheel, then the wheel will preserve a flat face. (See figs. 5 and 6.)

The ideal traverse per revolution of the work is about two-thirds the width of the wheel, but it should not, except for finishing, be less than half the width.

The table should travel as rapidly as can be used. (See '*cross feed*,' page 1117.)

The main factor governing production on external cylindrical grinding machines is the combination of wide wheels with fast table speeds, as, other things being equal, the machine which possesses these advantages is the most efficient tool.

The *work speed* has only an indirect effect on the output. With a good wheel it makes little difference to the finish obtained whether the work surface speed be, say, 30 or 60 ft. per minute, except that, if the lower speed is persisted in, it limits the table travel, and so in turn limits the output. For external cylindrical grinding the practice is to work on an average surface speed of 60 ft. per minute as a basis. Low work speed is directly conducive to distortion and inaccuracy. The heat created by the cutting action of the wheel must be dissipated or distributed as quickly as possible, and can only be done by a higher work speed and table travel aided by an ample flow of water.

Vibrations in the work itself and disintegration of the grinding wheel are more liable to occur in large diameter and heavy work than in small work. It is much easier to control vibration in small diameter work, and it would be almost impossible to rotate it at such a high speed as to disintegrate the surface of the wheel, but the tendency would be to cause unnecessary wheel wear, and if the table speed was such that the traverse was less than half the width of the wheel the later would wear more at the corners than in the centre.

Vibrations on heavy work are much more difficult to control, and much depends on the

* Abstract of Paper read by H. H. Asbridge before the Manchester Association of Engineers.

machine and method of supporting the work. No definite rule can be laid down, as so much depends on circumstances. For instance, it would be both permissible and advisable to run an 8-in. tube at a higher surface speed than an 8-in. solid shaft, the limiting factor in the tube being a surface speed such as would cause disintegration of the wheel face, there being no heavy body of metal to set up vibration, whereas in the shaft the limiting factor would be a surface speed sufficient to set up an oscillatory motion difficult to control, and which would prevent the shaft from being ground to a perfect cylinder. This same defect could also be obtained by using a too slow surface speed, due to insufficient dissipation of the heat created by the grinding wheel. Between these two extremes there is a wide margin of surface speed at which grinding can be sucessfully carried on.

A good rule is to get a wheel suitably graded for the work, and when once a suitable grade is found it should be recorded, as wheels such as are made from artificial abrasives can be duplicated within very fine limits.

The *cross feed* to the grinding wheel should operate at each reversal of the table, that is, at the end of each stroke; this is necessary to distribute the work over the whole width of the grinding wheel. Production is not governed so much by the amount of cross feed as by other conditions. There should be as much cross feed as the work, the machine, or the grinding wheel will stand; this will be from ·0005 in. to ·0015 in. on the work diameter at each reversal of table. Under these conditions, a machine with a fast table travel will give maximum output with a comparatively light cross feed, as compared with a machine having only a slow table speed, and will have the advantage also of not stressing the work to the same extent. The wheel will remove more material for a given wheel wear, and the machine will be more economical in power.

Over-run of work should be avoided (see p. 1119).

The *time required* in external grinding cannot be calculated with any approach to accuracy on the usual basis of cutting speed and feed, etc.

The finish grinding of a shaft of a given diameter and length is not a constant operation with an abrupt termination, as in other methods of machining, but is an operation starting at zero, rising quickly to the point at which possibly the maximum cutting capacity of the wheel is demanded, and then falling gradually to zero or finished size, and the finer the limit fixed for the finished diameter, the more gradual will be the closing stages of the operation. Grinding times must, therefore, so far as the wheel is concerned, be based on a mean of its cutting capacity, much lower than its maximum.

The formula, as deduced from the above method, is as follows:

Diameter of work in inches × length in feet × constant = grinding time in minutes for the removal of $\frac{1}{32}$ in. in diameter and finishing to commercial limit.

TABLE OF CONSTANTS.

Diameter of Work.	Size of Wheel.	Constant.
4-in. shaft and upwards.	26 ins. by 3 ins.	1·3
3-in. ,,	,,	1·4
2-in. ,,	,,	1·8
1½-in. ,,	,,	2·2
1-in. ,,	,,	3
3-in. shaft and upwards.	14 ins. by 2 ins.	2·2
2-in. ,,	,,	3
1½-in. ,,	,,	3·7
1-in. ,,	,,	5
3-in. shaft and upwards.	12 ins. by 1 in.	3
2-in. ,,	,,	3·8
1½-in. ,,	,,	4·5
1-in. ,,	,,	6·3

For the removal of $\frac{1}{32}$ in. in diameter allow $\frac{2}{3}$ of time obtained. For work below 1 in. diameter the grinding time tends to increase, depending entirely on rigidity of support afforded to same. Extra time should be allowed to special limits, such as may be required for drive fits, etc., or for special finished surfaces, such as are necessary for spindles, gauges, etc.

Centreless Grinding *

The objections to the use of centres to support the work during grinding, and the difficulty of accurately grinding gudgeon pins, crank pins, and other relatively long pieces of small diameter

* Particulars supplied by Dowdings' Machine Tool Co. Ltd., 38, Albert Embankment, S.E. 11.

can be avoided, and any irregularity caused by warpage in hardening removed by supporting the work in a suitable guide block. Two patterns (fig. 7) of guide blocks are used—one for rough grinding, and the other for finishing—the difference being in the relative positions of the three guide blades.

For rough grinding the near blade is adjusted so that the work projects beyond the lower front blade C, slightly more than the thickness of the material to be removed, whilst the upper blade, A, is given a clearance of 0·005–0·020 ins. In finishing, the upper and lower blades are more nearly vertical. The work is finished after it has been passed several times through the block.

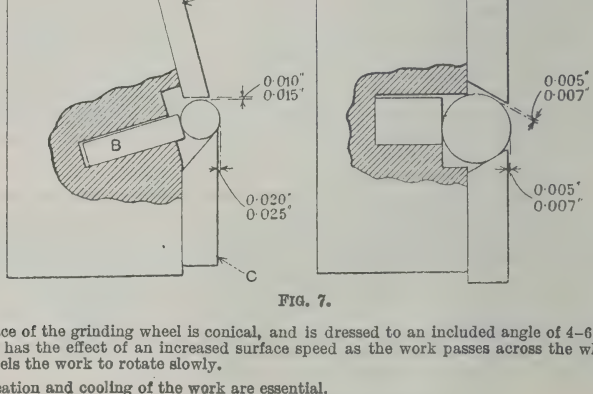

FIG. 7.

The face of the grinding wheel is conical, and is dressed to an included angle of 4–6 degrees, so that it has the effect of an increased surface speed as the work passes across the wheel face and compels the work to rotate slowly.

Lubrication and cooling of the work are essential.

The grinding is effected more rapidly than when centres are used.

Internal Grinding.

The idea that internal grinding cannot be satisfactorily accomplished at spindle speeds less than 30,000 to 50,000 r.p.m. is erroneous. Provided that there is rigidity in the spindle employed, the grinding-wheel diameter has little effect on production. The effective speed range of a good grinding wheel is very much greater than in any other form of grinding, and ranges from 1,000 to 4,000 ft. per minute, and much of the most successful grinding is done at the surface speed of from 1,500 to 2,500 ft., but a very rigid spindle is necessary.

There are two types of internal spindles, the ' tube ' type having a bearing immediately behind the wheel (this type is not to be recommended for holes, say, less than 6 ins. in length, as holes of this length, and longer, are generally insufficiently large in bore to admit of a substantial spindle), and the ' adaptor ' type. The construction of the latter type is such that the spindle bearings never enter the hole being ground, the wheel being carried on an adaptor fitted into the main spindle and held by a draw bolt, or, if the work to be ground is of limited range, the adaptor portion is formed integral with the main spindle. For general commercial work the loose adaptor is preferable, as long or short, heavy or light adaptors can be used suitable for the particular work in hand. The fact that the main spindle in this instance never enters the hole permits of it being made of liberal dimensions. The Churchill Machine Tool Co. fix the higher limit of such spindles at 1,500 r.p.m., and so long as the rigidity is there behind the adaptor no higher speed is necessary for holes from $\frac{1}{4}$ in. upwards.

The *wheel width* has a direct result on the output.

Given a spindle with the necessary rigidity, the use of wide wheels and a high table speed are the governing factors in obtaining maximum production. The standard practice of the above firm is to use all wheels from $\frac{1}{8}$ in. to 3 ins. diameter $\frac{3}{4}$ in. wide, above 3 ins. diameter 1 in. wide. Such wheels are of no advantage unless combined with high traverse speeds, in order to utilise as much of the wheel width as possible, and also to dissipate the heat generated evenly.

Table traverse speeds up to 9 ft. and 10 ft. per min. are commonly applied to internal grinding machines.

The *work speed* in internal grinding can be varied considerably above or below the speed which has been previously determined to be the best for the particular work in hand. Such variation would have very little effect on production, but might affect the finish obtained. In standard practice a work surface speed of from 100 to 120 ft. per minute is used as a basis or starting point, and varied according to circumstances.

The *cross feed* requires special care in internal grinding.

Whatever type of internal grinding spindle is used (where the work to be ground is carried on a rotating spindle) there is bound to be overhang from its supporting bracket, with more or less unavoidable spring, and whilst the slide carrying the spindle can be set to a predetermined position with great accuracy, it does not follow that the hole being ground will have reached the desired size, owing to the spring in the spindle. This fact makes the use of automatic cross feed almost impossible of accomplishment if the amount of the feed has to equal the amount of cut which the wheel will take at each traverse of the table. Hand-operated cross feed fitted with an adjustment dead stop is therefore to be preferred.

In another type of internal grinding, the work is stationary and the grinding wheel has imparted to it a planetary motion whilst rotating at a high speed on its own axis, the planetary spindle being eccentrically adjustable whilst grinding is proceeding. This type of machine has been employed for grinding motor-car cylinders when cast *en bloc*, and the possibilities of this type of machine for finishing holes are great.

Over-run of work should be avoided; that is, the wheel should never be allowed to leave the work, the traverse being only just sufficient to allow of not more than one-third of the width of the wheel projecting beyond the end of the work. If the wheel is allowed to run off, the result in external grinding will be to have the face of the wheel sheared away by the sharp ends of the work; and in internal grinding the hole will be bell-mouthed.

Surface Grinding.

There are two methods of surface grinding—one using the side of the grinding wheel,* and the other the edge of the wheel, carried on either a vertical or horizontal spindle, the more widely used being the vertical spindle type. The two methods are further subdivided according to the manner in which the work is moved, machines being made with the work carried on a reciprocating table, or on a circular revolving table, briefly classified as follows:—

1. Horizontal spindle surface grinding machine, where the work is reciprocated under the grinding wheel.

2. Horizontal spindle ring and surface grinding machine. In this machine the work is carried on a circular revolving table, generally made in the form of a magnetic chuck, and rotated under the grinding wheel.

3. Vertical spindle ring and surface grinding machine, where the grinding wheel is of cup form, carried on a vertical spindle, and the work is carried on a circular rotating table, generally in the form of a magnetic chuck and rotated under the wheel.

4. Vertical spindle surface grinding machine, where the wheel is of cup form carried on a vertical spindle, and the work is carried on a table reciprocating under the wheel.

The first and fourth types are the most commonly used, and intended for the grinding of flat surfaces of all kinds and in all materials.

The second and third types are widely used for grinding the sides of disc work, such as circular knives and saws, piston rings, disc valves, etc., using the rotary table. The second type of machine with the horizontal spindle leaves the work with a concentric finish, whereas the third type of machine with the cup wheel leaves the work with a radial finish, and which in some classes of work is objectionable, particularly, for instance, in piston rings, where the concentric finish is preferred. So far as production is concerned the vertical spindle ring and surface grinding machine will give a greater output than the horizontal spindle ring and surface grinding machine. Both machines can be arranged to grind flat, concave, or convex surfaces.

The most largely used machine for regular commercial purposes is the machine with the vertical spindle, owing to its greater productive capacity.

The best *wheel speed* for all-round surface grinding is about 4,000 ft. per minute, with very little margin of speed—that is, if a wheel is working successfully at 4,000 ft. per minute, it cannot be varied up or down from this speed without affecting production, consequently the vertical spindle machine with the cup wheel has a great advantage in this respect, due, of course, to the wheel retaining its diameter as it wears.

The grade of the wheel for surface grinding demands far closer attention than in any other type of grinding. The only remedy for a wheel that is too hard or too soft is to change it for a wheel of the correct grade.

* Grinding on the flat sides of straight wheels is often hazardous, and should not be allowed. Cup or ring wheels should be used.

A high *table speed* is the main factor governing output, using suitable grinding wheels, but the machine which will so work that the temperature is even throughout the whole ground surface will produce the most accurate results.

The vertical surface grinding machine with the cup wheel, which covers the full width of work at each stroke of the table, has a distinct advantage over the horizontal spindle machine using the periphery of the wheel, and which would have to be traversed transversely in order to cover a work surface wider than the width of wheel.

Quite apart, however, from the question of heat distribution, the vertical spindle machine has the greater productive capacity, and for grinding wide surfaces or groups of small articles this type of machine has the advantage of the horizontal spindle machine. The vertical surface grinding machine is now being adopted in all classes of engineering works, and wherever flat surfaces have to be produced, such as in machine-tool work, there is no method that can be compared with it for cheapness of production.

A machine of this type added to the equipment of any works, and used for the production of flat surfaces has, more than any other type of grinding machine, a beneficial effect throughout the works, and in this respect raises automatically the standard of work produced. In this way, given an accurate machine, it is so very easy to true up straight edges and similar tools and keep them all in a constant high state of perfection; and by having a machine of this type always in readiness to produce flat surfaces the result is that more accurate work is automatically produced throughout the works.

The *time required* for grinding a given surface can be ascertained with fair accuracy once a basis is found, based on area ground and amount of metal removed. Under normal working conditions, a grinding wheel has a certain capacity for the removal of metal, based on its cutting area or its diameter and width.

Wear of Wheels in Grinding.

The following examples will serve to show what may be expected from wheels which are suited to the conditions and work in hand :—

A batch of 72 soft steel spindles of diameters ranging from 1½ inch down to $\frac{9}{16}$ inch by 8 inches long, and having from ·010 to ·015 inch left for grinding, were finished in an average time of 4½ minutes each. The wheel was Norton 'Alundum' 60.M, running at a speed of 6,500 ft. per minute, and it lost ·0005 inch diameter for every six spindles ground. The work speed was 30 ft. for $\frac{9}{16}$ diameter, and 60 ft. for 1½ inch diameter, and the grinding limit was ·00025 inch.

Cast-iron spindle tubes 2½ inches diameter by 12 inches long took an average time of 10 minutes each to finish. The grinding limit was ·00025 inch, and the amount removed ·010 to ·015 inch. The wheel was Norton 'Alundum' 46.H, running at 5,500 ft. per minute, and it lost ·001 inch in diameter on every tube. The speed of the work was 30 ft. per minute.

These examples are given as indicating an amount of reduction in wheel size which should not be exceeded under ordinary conditions. (*Churchill Machine Tool Co., Ltd.*)

Grinding Allowances.

(For Norton and Heald Grinding Machines.)

Frequent inquiries as to the amount of stock which should be left on turned and bored work to be ultimately finished to size by grinding had led to the answer that this depends on several factors which must be ascertained before a correct allowance can be determined. The object aimed at should be to so proportion the work between the lathe and the grinding machine that the total time taken by both in producing the desired degree of finish and accuracy is reduced to the minimum.

In a desire to turn out a 'good job' the turner sometimes overlooks the fact that a smooth piece of work having only a small allowance may take as long to finish in the grinding machine as a rough-turned job on which more metal is left.

The chart, fig. 8, shows the grinding allowances which are recommended for turned or bored work up to 12 ins. diameter. Although the amounts specified may, to some, appear excessive, they may be allowed with confidence in establishments possessing a grinding department run according to modern ideas of efficiency and lathes sufficiently powerful to take the coarse feeds recommended.

Curves A and A¹ show maximum and minimum amounts to be left on the diameter of rough turned work over 12 diameters long.

Curves B and B¹ show maximum and minimum amounts to be left on the diameter of rough turned work under 12 diameters long.

Curves C and C¹ show maximum and minimum amounts to be left on diameter of smooth turned and bar-lathe work over 12 diameters long.

Curves D and D¹ show maximum and minimum amounts to be left on diameters of smooth turned and bar-lathe work under 12 diameters long.

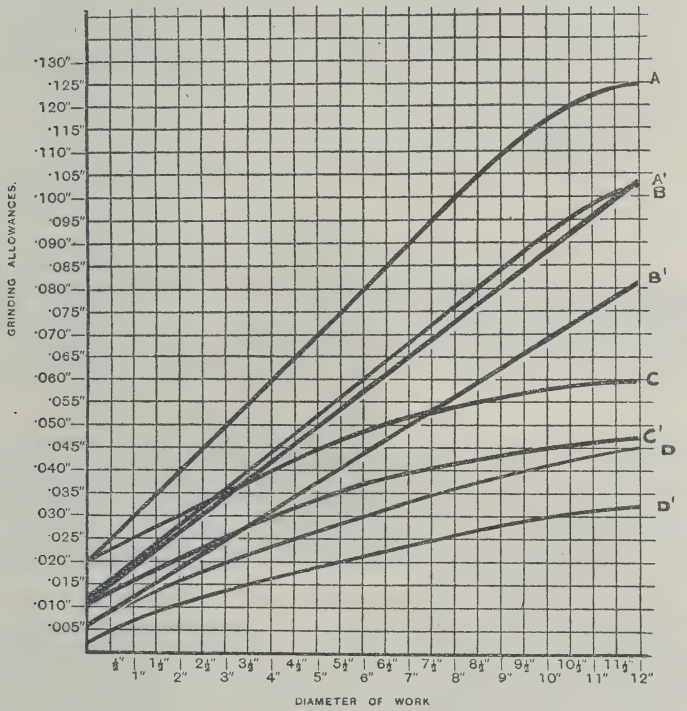

FIG. 8.—Grinding Allowances for Norton Cylindrical Grinding Machines.

NOTE.—By 'rough turned,' is meant work having coarse traverse marks, the measurements being taken on the top of the ridges. The following are the finest feeds which should be employed :—

For work up to 2 ins. diameter	30 per inch
For work from 2 ins. to 4 ins. diameter	20 ,,
For work from 4 ins. to 8 ins. diameter	16 ,,
For work from 8 ins. to 12 ins. diameter	8 ,,

Case-hardened work is an exception, because the finish must be fairly smooth to allow regular penetration of the casing compound. Use curves C and C¹ for all such work.

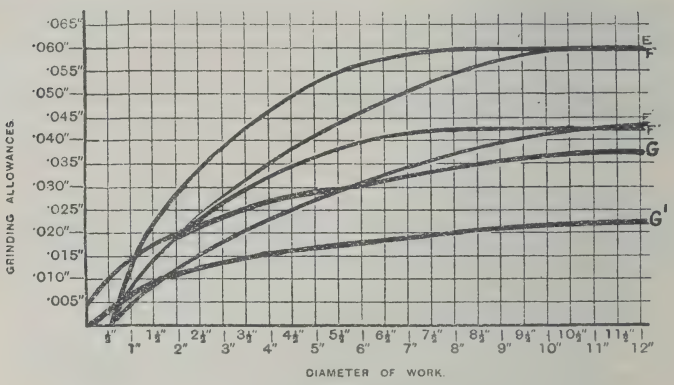

FIG. 9.—Grinding Allowances for Heald Internal Grinding Machines.

Curves E and E′ (fig. 9) show maximum and minimum amounts to be left in the bore of mild steel work that is to be case-hardened before grinding.

Curves F and F¹ show maximum and minimum amounts to be left in the bore of carbon or high-speed steel work that is to be hardened before grinding.

Curves G and G¹ show maximum and minimum amounts to be left in the bore of soft work, whether steel, cast iron, or brass.

NOTES.

The following explanatory notes will serve to show the theory followed out, and will assist in determining allowances for the exceptional jobs which will occasionally present themselves:—

Taking first *external work*, as being the more common, it will be noted that a larger allowance is made on articles which exceed twelve diameters length than in the case of shorter jobs. This is to save lathe work.

A job over twelve diameters long will spring considerably under a good cut, and there is a possibility of bends making their appearance. The largest possible allowance is therefore made on this work, so that the turner need not waste the time which would be taken in producing articles more nearly parallel and straight.

Then, again, a distinction is made between rough-turned work and that which is produced by a fine feed or made on turret lathes with a box tool.

For all work turned between centres, with the exception of that which is to be carbonised for case-hardening, the use of a coarse traverse is advocated, the finest feed per inch that should be used for various diameters being specified on the chart. Work which is to be carbonised must be turned with a fairly smooth finish, so as to allow regular penetration of the casing compound; therefore the allowance specified for smooth work over twelve diameters long should be used for case-hardened work whatever its length. If such work is hollow it may distort after quenching, therefore great care must be exercised in hardening, as the allowance above specified cannot be exceeded or the hard skin would be entirely removed in grinding to size.

The allowance for carbon and high-speed steel work which is hardened will be the same as that provided for soft work, as any distortion which occurs must be corrected in the straightening press before grinding.

Internal work, which is dealt with by the lower portion of the chart, is divided into three classes as follows:—

1. Mild steel case-hardened.
2. Carbon or high-speed steel hardened.
3. Soft work, whether steel, cast iron, or bronze.

Hardened and case-hardened work in which the hole is less than half an inch in diameter should, as shown in the chart, be bored or reamed to standard size, as there will be a sufficient

shrinking when the quenching takes place to provide a grinding allowance. It will be noted that the amount allowed in case-hardened work increases very rapidly up to 6 ins. diameter; this is to allow for distortion in hardening. Above this size the increase is slow, and care should be taken to avoid excessive distortion, as no larger allowance can be made, otherwise the hard skin would be removed by the grinding operation. In determining the allowance for soft work it should be remembered that the class of finish given to the hole will decide whether the high or low limit should be worked to. Thus, in holes which are rough drilled or bored, the allowance should approach the maximum, whilst in reamed holes the minimum allowance should be left.

(*Alfred Herbert Ltd., Coventry.*)

Polishing.

For grinding and polishing *marble, stones*, and *glass*, crushed steel has proved very satisfactory, on account of its hardness, sharpness and toughness. It is, however, but little used in this country, sand, carborundum or aluminous abrasives being generally employed. For cutting stone, marble, and glass, a metal wheel with loose sand and water is largely employed, but grinding wheels of carborundum and aluminous abrasives of medium grade and 36–50 grit are being increasingly employed. For producing a rough surface on glass, the sand-blast process is largely used.

For *smoothing wood* and similar materials, garnet-emery and sand, mounted on paper or cloth, are largely employed, garnet being especially suitable for hard woods. For finishing wooden handles, sand mounted in endless belts is largely used.

In the leather industries, and especially in the manufacture of boots and shoes, corundum and carborundum cloths are largely used for heel scouring and breasting and for buffing.

For work in which an *exceptionally hard abrasive* is required, including the truing of abrasive wheels, diamond bort or carbonado are employed.

For polishing steel articles, blocks of carborundum or aluminous abrasive or cloth or paper covered with emery or corundum is largely employed.

For polishing other metals, glass, etc., loose powders are employed. Such powders may be used in the dry or wet state, and may be rubbed on to the material to be polished, or they may be applied by means of a wheel (or 'dolly') composed of discs of cloth.

For polishing brass and other softer metals, very fine silica, quartz flour, emery carbide or aluminous abrasives, crocus, rouge, or whiting are employed. For silver and gold, well-slaked lime is largely used. The polishing powder is sometimes treated with rouge to disguise its nature and to give white metals a slightly ruddy tint, which improves their appearance.

In the so-called liquid polishes, a little oxalic acid or other chemical detergent is sometimes added to the abrasive powder, or to the liquid in which the latter is suspended.

Power required for Emery Polishing.

Using a calico mop, 12 ins. diameter by 2 ins. wide, it is usual to run these at a speed of 10,000 feet per minute. The average resistance at the circumference of a well-loaded wheel is about 10 lbs., and this would give a h.p. for the mop equal to 3. To this has to be added the friction of the spindle in its journals, and this will depend on the nature of the journal (whether plain or ball), and also the lubrication. The friction is principally due to the pull of the strap, and if its spindle is taken to be 1½ in. diameter, and the value $\mu = \cdot 075$, the frictional h.p. would be about ·25, and if a further ·25 be allowed for acceleration, the h.p. to drive the machine would be 3½. For a 10 in. diameter buff the h.p. would be proportionately less—that is, ab out 3.

Sand Blasting.

The air pressures used for different materials are, approximately, as follows:—Steel castings or forgings, 80 to 100 lbs.; malleable iron, 70 to 85 lbs.; cast iron, 60 to 70 lbs.; and brass and aluminium, 35 to 50 lbs.

For some classes of work a small nozzle opening, that is, a fine strong jet, may be desirable; for other work a broader stream, covering a larger surface but working at a lower pressure may be best. Table I. gives the relation between air flow in cubic feet of free air per minute at varying pressures, and the horse-power required to produce them by single-stage compression, for nozzles ranging in diameter from ⅛ to ⅜ in. inclusive.

Typical cylinder dimensions, together with the displacement and the horse-power required to develop various amounts of air pressure, are given in Table II.

In cases where there is moisture in the air, it is well to make provision for the elimination of the moisture by installing a moisture separator or a suitable heater.

Sand is the most commonly used abrasive on account of its relatively low price. Ordinary sand is inferior to sharp sand and crushed silica, as the two latter possess greater cutting power and are therefore more effective. Abrasives such as steel grit and shot are used to a certain extent, and the use of these more expensive abrasives is warranted under certain conditions. For classes of work such as electro-plating or galvanising, the metallic dust adhering to the work prohibits the use of carborundum, because it prevents perfect galvanising, although no difficulty is experienced in this respect with sand.

There is no one abrasive that is best adapted to all classes of work. A selection must be made with due regard to reclaiming means, to greatest economy in operation, and to maximum production. By making tests with various materials, and keeping accurate records of quality of work, output, life of the abrasive, and so on, the one best suited for the individual application is readily determined. Such tests have shown metal abrasives to have about sixty times the life of sand. This apparently large percentage may, however, be offset to a great extent by losses of abrasive in operation or in handling. In good steel foundry practice these losses may be kept as low as 10 per cent., while the average loss due to disintegration, for different grades of sand, amounts to about 20 per cent. per month. The reduction in cleaning time resulting from using metal abrasives instead of sand varies, of course, but a gain of about 15 to 20 per cent. in time appears to be in line with actual practical experience. Metal abrasives do not require large sand-storage bins and have the added advantage of producing less dust, thereby improving the general working conditions.

TABLE I.—FLOW OF FREE AIR FOR DIFFERENT SIZES OF NOZZLES.

Diameter of Nozzle. Ins.	Pressure (cub. ft. per min.) and Corresponding Horse-power Required.							
	20 lbs.	H.P.	30 lbs.	H.P.	40 lbs.	H.P.	50 lbs.	H.P.

TABLE II.—CYLINDER DISPLACEMENTS AND HORSE-POWER REQUIREMENTS OF AIR COMPRESSORS.

Cylinder.		Revs. per min.	Piston Displacement. Cub. ft. per min.	Horse-power Requirements. Pressure (cub. ft. per min).					
Diam. Ins.	Stroke. Ins.			50	60	70	80	90	100
6	6	300	57	7	7·5	8·5	9·0	9·5	10
8	8	260	118	14	15·5	16·8	18·0	19·0	20
10	10	235	210	24	27·0	29·0	31·0	33·0	35
12	12	220	340	45	50·0	54·0	58·0	62·0	65

All abrasives should be screened each time before using, to remove particles large enough to clog the nozzle, and also to eliminate fine particles which only produce dust and have no abrasive quality, but which consume some of the pressure. Screen separators, frequently operated by compressed air, may be used for this purpose. (*Abstract, C.M.S., 'Machinery,' Jan.* 13, 1921.)

SECTION XXI

PART III

STEAM-HAMMERS.

(Messrs. B. & S. Massey, Ltd., Openshaw.)

Three standard types of steam-hammer are made by B. & S. Massey, Ltd.—the 'Overhanging Form with Slides,' the 'Arch Form with Slides,' and the 'Rigby type without Slides.' All these hammers can be made suitable for driving by compressed air instead of steam.

Overhanging Form with Slides.

These hammers (fig. 1) are usually preferred for general smith-work. The anvils are accessible to the workman from three sides, and the tups are supported and accurately guided by the slides, making it possible to do accurate stamping in dies.

Each hammer has two separate standards, with a space between them, through which long bars can be passed. All the hammers are double-acting and are fitted with equilibrium working valves.

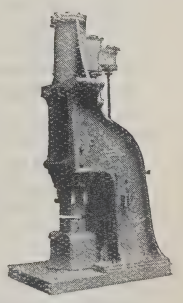

Fig. 1.

Up to and including the 12-cwt. size, the hammers are fitted with a combined self-acting and handworked valve gear; the 15-cwt. and larger sizes are ordinarily fitted with Massey's Handworked Expansion Valve Gear, but a combined self-acting and handworked gear can be fitted if desired.

The pistons, which are forged solid with the piston-rods, are fitted with steel piston-rings. The palletts are made of tough forged steel with planed and hardened faces.

The anvil blocks are about 8 times the weight of the falling mass, and in the 12 cwt. and smaller sizes they are turned to fit the bored baseplates; this greatly increases the efficiency of the hammers when it is desired to use them for stamping in dies.

DIMENSIONS, WEIGHTS, AND MEMORANDA OF OVERHANGING FORM STEAM-HAMMERS WITH SLIDES.

Standard sizes	½ cwt.	1 cwt.	1½ cwt.		3 cwt.

(*b*) Average on mixed blows	170 lbs.	195 lbs.	228 lbs.	275 lbs.	330 lbs.

* All these figures are necessarily rough approximations.

They are meant to apply to average engineers' smithwork, and are for efficient results on this class of work, with a steam pressure of about 60 lbs. per sq. in.

Even for this they may for occasional jobs be considerably exceeded.

There are many classes of work which require much larger hammers, and some classes which require smaller hammers than those indicated, owing chiefly to the varying amount which has to be done at a heat.

† Steam Consumption.

A steam pressure of about 60 lbs. per sq. in. is assumed.

During ordinary forging there are many blows of less than full force, and there are also necessary pauses (holding up) for adjusting work or tools during a heat.

While line (*a*), page 1126, gives the consumption on continuous hard blows only, line (*b*) gives the consumption as ordinarily reduced by these circumstances. Further, under average smithy conditions, a hammer may be assumed to be actually in motion about 15 minutes in every hour and the figures given in line (*b*) are based on this assumption.

In cases in which one boiler is put down solely to drive one hammer, the capacity of such boiler should be fixed according to line (*a*), page 1126, because otherwise the pressure would fall too low during a normal run of hard blows.

Arch Form with Slides.

These hammers, fig. 2, are made in sizes ranging from 3 cwt. to 10 tons and over, and the design provides a maximum of strength and rigidity. The 15 cwt. and larger sizes are fitted with Massey's Handworked Expansion Valve Gear.

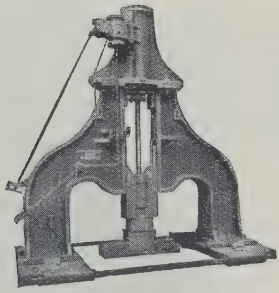

Fig. 2.—Arch Form.

Rigby Type without Slides.

These hammers, fig. 3, which are made in sizes from 3 cwt. to 3 tons, are particularly suitable where forgings of large size and awkward shape have to be dealt with. The strokes are longer

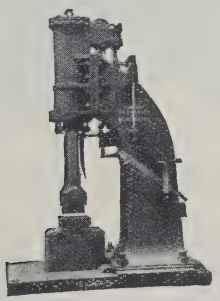

Fig. 3.—Rigby Type.

and the cylinders larger in diameter than in the other forms described. All sizes are fitted with Massey's Handworked Expansion Valve Gear.

Energy and Velocity of Blow.

If

a = area of piston, in square inches : p = average pressure of steam on piston during downward stroke, in pounds per square inch : S = stroke of piston, in feet : W = falling weight in pounds : E = energy of blow after full stroke and before striking, in foot-pounds, friction being neglected ;

$$E = (ap + W)S.$$

If

P = total pressure on piston = pa : F = total force causing downward acceleration = $P + W = pa + W$: g = acceleration due to gravity = 32·2 : V = velocity after full stroke and before striking, in feet per second, friction again being neglected ;

$$V^2 = \frac{2F\mathcal{g}S}{W}.$$

No commercial use is made of these calculations, either for the naming of sizes of hammers or for any other purpose.

The question is sometimes asked : *What weight of blow does the hammer strike?*

The force of a blow cannot be stated in terms of weight at all, because the pressure of a weight is continuous, whereas the force of a blow is expended in a moment. It has, however, been ascertained, by careful experiments, that the maximum blow of a 5-cwt. double-acting steam-hammer, with moderate steam pressure, produces a crushing effect upon a piece of hot iron as great as that produced by a load of about 30 tons, and a ½-cwt. double-acting steam-hammer a crushing effect equal to that produced by a load of about 2½ tons.

Naming Sizes of Steam-hammers.

In naming the sizes of steam-hammers, no account is taken of the pressure of steam upon the piston. Thus, a 5-cwt. hammer is one in which the falling mass weighs at least 5 cwt., but of course the force of the blow is greatly increased by the pressure of steam above the piston accelerating the fall.

Steam Pipes for Steam Hammers.

See 'Steam Pipe Bends,' Section XXX, Part II.

Foundations.

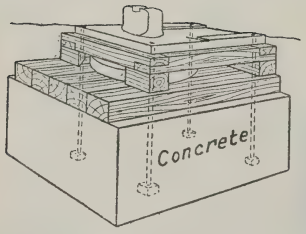

FIG. 4.—Typical Foundation for Steam-Hammers of the Overhanging Form.

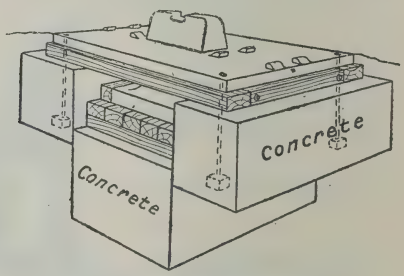

FIG. 5.—Typical Foundation for Steam-Hammers of the Arch Form.

(*B. & S. Massey, Ltd.*)

The Steam Hammers of the Overhanging Form, the Arch Form, and the Rigby Type per pp. 1125–1127 can all be driven equally well by Compressed Air, the clearances being suitably reduced.

PNEUMATIC POWER HAMMERS.

Massey Patent Pneumatic Power Hammers, Overhanging Form with Slides.

These hammers (fig. 6) are arranged for belt or for direct electric drive. They are similar to steam-hammers in many respects, and are about equal to them in working capacity, assuming the steam-hammers to be working under ordinary conditions of pressure, etc.

It is very important to note that the size name of each hammer indicates the true weight of its falling parts.

The anvil block is set diagonally, to enable long bars to be worked in either direction.

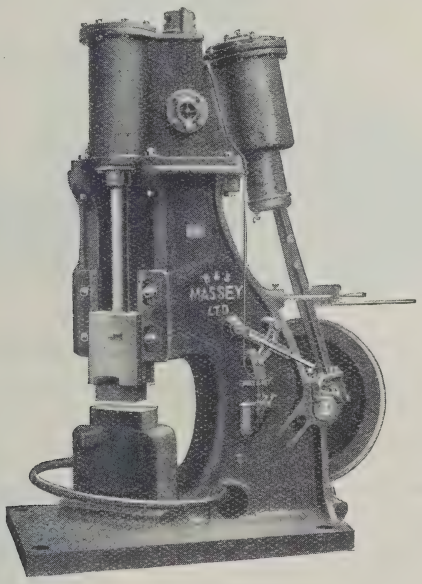

Fig. 6.

The essential feature of the hammers lies in the connecting together of two cylinders—the hammer cylinder and the pump cylinder—by air passages which are governed by a valve under the control of the operator. See fig. 7, p. 1130.

When the piston reciprocates with the valve in the 'not working' position (as shown) air flows freely through the valve from one side of the piston to the other. The tup therefore remains stationary on the anvil.

As the valve is moved upwards the by-pass through the valve is gradually closed, so that when position 4 is reached, all the air is forced from the top of the pump to the top of the hammer, and from the bottom of the pump to the bottom of the hammer, thus producing full-force automatic blows. The positions intermediate between 3 and 4 provide a wide variation in the character of blow and the length of stroke.

With the valve in position 1, the reservoir is charged from the top and bottom of the pump and is, at the same time, in communication with the bottom of the hammer. This gives a perfectly smooth rise and a steady 'Hold-up.'

When the valve is moved to position 2, the bottom of the hammer is opened to atmosphere, and compressed air from the reservoir passes into the top, thus throwing down the tup and striking a single blow.

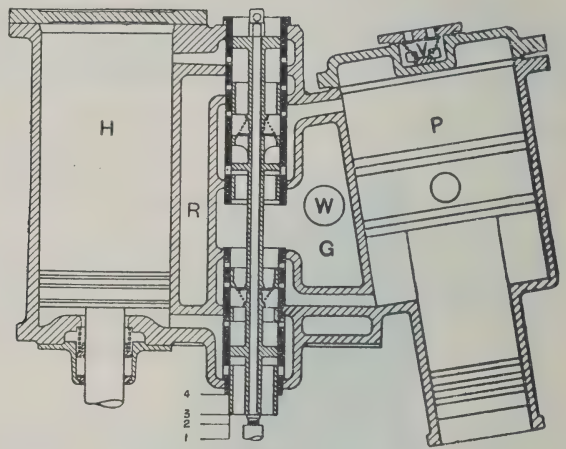

FIG. 7.

While the valve is kept in this position, the tup is held down with full pressure above the piston.

Inlet valves V and W supply air to the top and bottom of the system.

(*B. & S. Massey, Ltd.*)

Massey Patent Pneumatic Power Hammers.

Arch Form with Slides.

These hammers, fig. 8, are made in the 30 cwt. and 40 cwt. sizes, and are arranged for 'direct electric drive.' The action and control of the hammers is identical with that of the overhanging

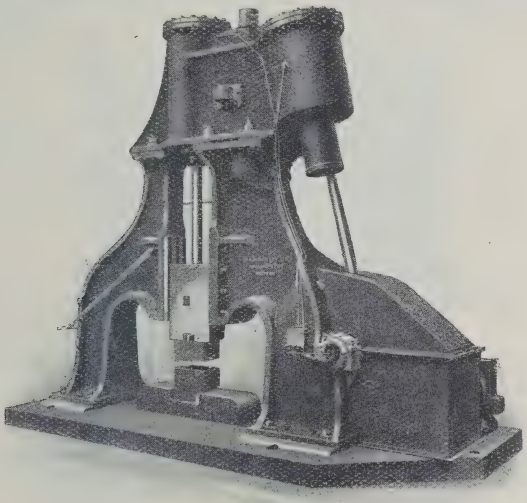

Fig. 8.

form with slides (pp. 1129-30), *i.e.* 'Single Blows' may be struck from any point in the stroke. each requiring a separate movement of the hand lever, or a series of automatic blows may be obtained of any desired force and with long or short strokes.

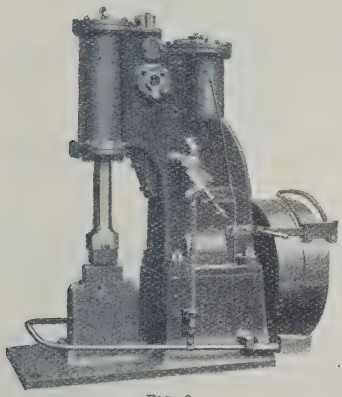

Fig. 9.

'Clear Space Type without Slides.'

These hammers also are identical in action and control with the hammers of the overhanging form with slides (pp. 1129–30). As will be seen from fig. 9 ample clear space is provided for the manipulation of large and awkward forgings, by dispensing with Slides and adopting a special Stuffing Box to guide the rod.

The hammers can be belt or motor driven, and provided with a foot lever in addition to the hand lever, if desired.

DROP STAMPS.

The Massey Friction Drop Stamp.

The practice of Stamping, in Dies, parts which have to be made in large numbers, such as motor-car parts, railway wagon parts, etc., etc., has become very general, and the tool usually adopted

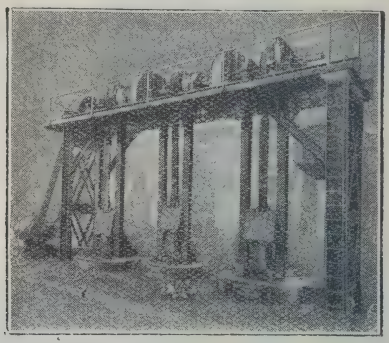

Fig. 10.—Battery of 30-15-20 cwt. Friction Drop Stamps.

for this purpose in this country is the 'drop stamp.' Latterly, the friction lifted type of drop stamp (fig. 10) has tended to supersede the steam lifted type, on account of the improved control, the greater efficiency and the smaller cost of up-keep.

Battery Form.

The usual plan is to have two, three, or four drop stamps of different falling weights arranged in a battery. The lifting mechanism in this case is mounted on girder work supported on stanchions, while the falling weight or tup is guided by vertical rolled steel guides resting in recesses in the anvil block, and supported at their upper ends by the girder work in such a way as not to transmit shock to the lifting mechanism.

Rigid Guides.

Where multiple impression dies are used, or specially accurate die alignment is required, rigid cast-steel guides can be substituted for the ordinary guide bars.

Self-contained Form.

As an alternative to the battery form, 40 cwt. and smaller stamps can be self-contained, with cast-iron guides secured to the anvil block carrying a cast-iron 'cradle' in which the lifting mechanism is arranged (see fig. 11).

Details of Friction Lifters.

The lifters themselves resemble a band brake in construction. A steel brake band lined with suitable material, and connected with the lifting arm, is made to grip a constantly revolving drum by means of a lever actuated by hand through a pulling cord, and the tup is thereby raised. As soon as the tension on the cord is released, a spring disengages the band, and the tup falls under the influence of gravity.

A special arrangement is adopted by means of which the grip of the friction band is automatically reduced as the tup rises, thereby making it necessary to maintain a constant pull on the cord in order to prolong the rise of the tup; when, moreover, the cord is held stationary, the tup remains suspended at the point to which it may have been raised, and as stated above, the tup falls when the tension on the cord is released.

It will therefore be seen that a very intimate relation exists between the movements of the tup and those of the pulling cord.

The movement of the hand is only a short one, and the pull required is very slight, but every movement of the hand is reproduced on a larger scale by the tup. Those who are familiar with the old-fashioned kick stamps in which a heavy pull was required the whole length of the stroke, and which sometimes required two or three men to act as pullers, appreciate very highly the action of friction stamps in which a control as excellent as in the kick stamp is secured with so little labour on the part of the operator.

Method of Driving.

The friction lifters are generally mounted on shafts driven by spur gearing from a quick-running back shaft. A flywheel which also serves as a driving pulley is mounted on one end of the back shaft and supplies the reserve of power needed at the moment of picking up the tup.

The drive is usually taken direct from an electric motor placed either on one of the stanchions or in the larger sizes on the floor, or in some other convenient position.

Simplex Automatic Gear.

For certain classes of work, especially stampings made straight from the bar, it is an advantage for the stamper to be able to control the stamp himself, thus saving the cost of a driver. The Massey patent 'Simplex' automatic gear achieves this by combining a foot-operated hold-up gear with a reversing gear which causes the tup to rise and fall automatically.

When the foot lever is held down the tup falls, and continues to rise and fall until the foot lever is released, when it rises and is held up without consuming any power.

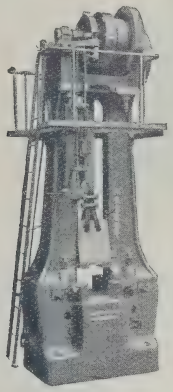

FIG. 11.

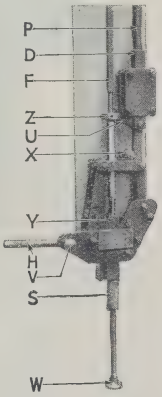

FIG. 11A.

The automatic action is obtained by means of a trip rod (F) which reproduces the movements of the tup on a small scale. The length of stroke can be adjusted by the sleeve (S) and the 'pick-up' by the hand-wheel (W), these adjustments deciding the points at which the toggle-mechanism is brought into and thrown out of action.

When the toggle levers are as shown in the illustration the spring (P) is compressed. As the collar (Z) strikes the lip (U) the toggle levers are thrown across and the spring comes into action, tightening the pulling cord and causing the tup to rise. The trip-rod then also rises, the cam (Y) eventually comes into contact with the roller on the lower toggle lever and the spring is again compressed, allowing the tup to fall.

By means of the hand lever (H) the automatic gear is thrown out of action and the stamp can then be worked by hand in the ordinary way.

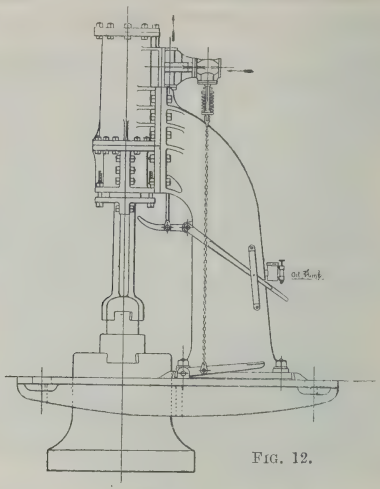

FIG. 12.

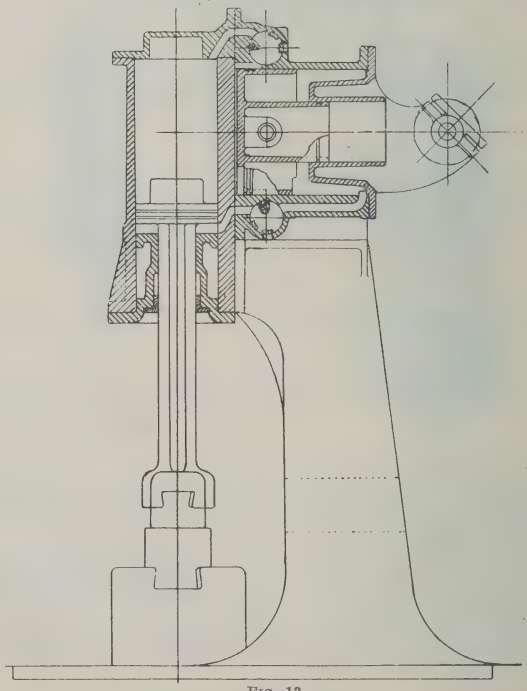

FIG. 13.

'Rigby's Patent' Hammers.

(R. G. Ross & Son, Ltd., Greenhead, Glasgow.)

The 'Rigby's Patent' Steam and Compressed Air Hammer, made by R. G. Ross & Son, Ltd., for very many years, is so well known that it hardly calls for description. In the single column form, illustrated by fig. 12, it is completely open on three sides and is quite without external guides. Owing to this open construction, it is much employed for general smith's work. The cylinder unit is of exceptionally strong construction, having a heavily flanged external mouthpiece or stuffing box which is bolted direct to the column flange, thereby taking all the working stresses and strains off the cylinder proper, and greatly increasing the life of the hammer. The ingot steel piston rod, forged in one piece, is machined, highly polished, provided with two flats and fitted at the lower end with a hammer face of high tensile steel. The mouthpiece and gland together provide a long guide for this piston rod, corresponding flats being machined in both. The gland, which is of steel, is lined with white metal to ensure a perfectly smooth bearing for

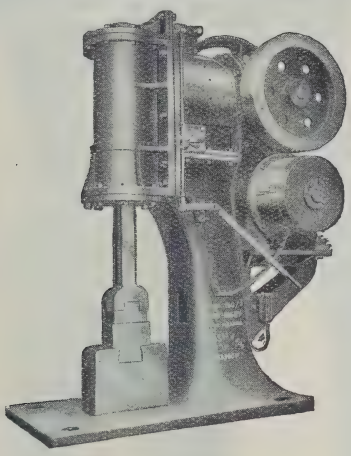

Fig. 14.

the piston rod, and flats are also machined on the outside of this gland to take all twisting strains off the adjusting gland bolts.

A double column form, also without external guides, is made by the firm, the cylinder being supported on heavy built-up girder work.

The 'Ross-Rigby' motor-driven pneumatic power hammers are constructed on the same principle, as may be readily gathered from fig. 13. The main parts of this hammer comprise a horizontal compressor with a piston of trunk type, a driving motor geared to a crankshaft, which drives the compressor, and, finally, the working cylinder and its various parts. Two interconnected rotary valves control the movement of the hammer piston, whilst for 'holding-up' and 'holding-down' springless non-return valves are employed. These hammers are made in sizes from 2 cwt. up to 10 cwt. falling weight.

Drop-Forging Equipment.

(Brett's Patent Lifter Co., Ltd., Coventry.)

Drop-forgings now form an essential feature of most engineering propositions and are, in fact, indispensable in the economical construction of automobiles, aeroplanes, agricultural machinery, railway rolling stock, locomotives, carriages, and waggons.

Types of Hammers.—Drop-hammers are generally constructed in battery form containing three or more hammers of varying sizes, or, alternatively, each hammer can be constructed as a single self-contained unit, as shown in fig. 15. The lifter or apparatus for controlling the tup is a very important feature of a drop-hammer, and two main types are in use, *i.e.* suitable for

operating with steam or compressed air, or, alternatively, what is known as the friction type, which is driven by electric motor, or belt power. The question of installing one or the other depends entirely upon convenience of power. Large drop-hammers of 5 tons and upwards are

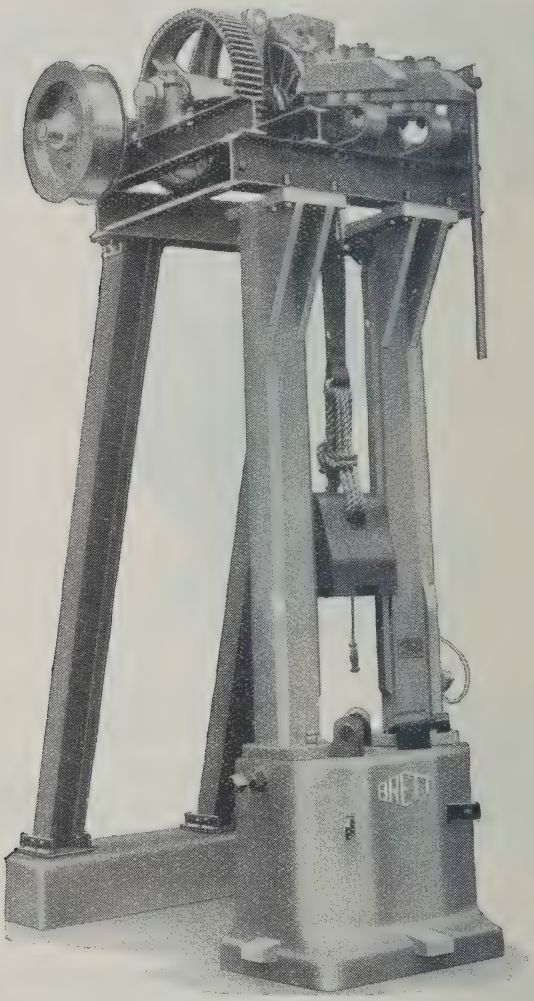

FIG. 15.

economically driven by means of a tubular boiler fired by the waste heat from the furnaces. Small hammers are frequently arranged in self-contained form, the usual standards being dispensed with.

SECTION XXII

SCREW THREADS AND SCREWS—BOLTS AND NUTS—LOCK NUTS—SPANNERS—PIPE FLANGES—KEYS—SCREW TAPS—COUPLINGS—PULLEY ARMS AND BOSSES.

(Revised by Professor Dempster Smith, M.B.E., M.Sc.Tech., M.I.Mech.E.)

SCREW THREADS AND SCREWS.

Forms of Screw Threads.

Figs. 1, 2, 3, and 4 show four usual forms of thread, each of 1 inch pitch.

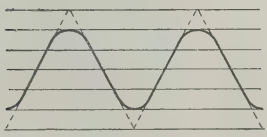

FIG. 1. Whitworth Thread-form.

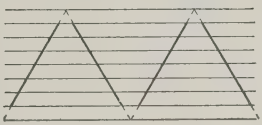

FIG. 2. American Thread-form.

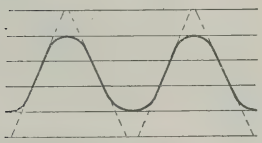

FIG. 3. Swiss Thread-form.

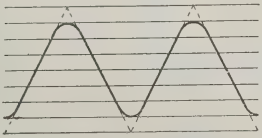

FIG. 4. Steinlen Thread-form.

In the *Whitworth* or *English Standard* thread (fig. 1) the angle made by the two sides of the thread is 55° for all sizes of thread. One-sixth of the depth of the triangle is rounded off the top and bottom, so that the angle of 55° gives for the actual depth rather more than three-fifths and less than two-thirds of the pitch.

In the *American (Sellers')* thread (fig. 2) the angle made by the two sides of the triangle is 60°, and one-eighth of the depth is cut off the top and bottom of the triangle, leaving a flat one-eighth of the pitch in width.

In the *Swiss* or *Thury* thread (fig. 3) the angle made by the two sides of the thread is 47½° and one-fifth of the depth is rounded off the top and bottom of the triangle.

For screw-plate Swiss threads the depth of the thread is three-fifths the length of the pitch.

The top of the ridge is formed by a circular arc, the radius of which equals one-sixth of the pitch. The space between two consecutive ridges is formed at the side next the core by a circular arc, the radius of which equals one-fifth of the pitch.

The Swiss thread for screws made in the lathe is the *Steinlen* thread (fig. 4). The angle made by the two sides of the thread is 58° 8′, and the radius of the connecting arcs is ·1011 of the pitch. The generating figure is an isosceles triangle, of which the base and the height are equal to the pitch. One-eighth of the depth is rounded off the top and bottom of the triangle.

The *British Association* thread is similar to that of Thury, except that the top and bottom of the threads are both rounded to the same radius, namely, two-elevenths of the pitch.

Screw Threads

Whitworth's Standard Threads.

BRITISH STANDARD FINE (B.S.F.) SCREW THREADS AND THEIR TOLERANCES.*
(No. 84—1918.) (*Abstract.*)

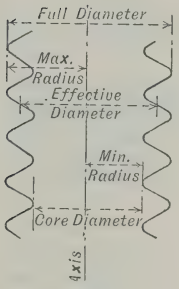

FIG. 5.

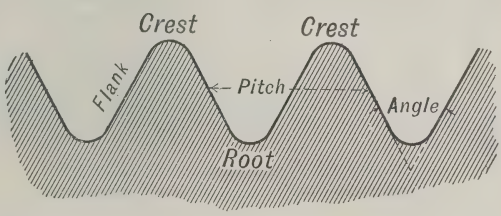

FIG. 6.

Effective Diameter of a Screw.—The effective diameter of a perfect screw having a single thread is the length of a line drawn through the axis and at right angles to it, measured between the points where the line cuts the flanks of the thread (fig. 5).

Core Diameter.—The core diameter is twice the minimum radius of a screw, measured at right angles to the axis (fig. 5).

NOTE.—From fig. 5 it will be seen that the 'core diameter' of the male thread is measured between the roots of the thread; it should be borne in mind, however, that the 'core diameter' of the female thread, being approximately the same dimension, is measured between the crests of the thread.

Full Diameter.—The full diameter is twice the maximum radius of a screw, measured at right angles to the axis (fig. 5).

Crest.—The crest is the prominent part of the thread, whether of the male screw or of the female screw (fig. 6).

Root.—The root is the bottom of the groove of the thread, whether of the male screw or of the female screw (fig. 6).

* By permission of the British Engineering Standards Association.

Flank of Thread.—The flank of the thread is the straight part of the thread which connects the crests and roots (fig. 6).

Angle of Thread.—The angle of the thread is the angle between the slopes, measured in the axial plane (fig. 6).

Pitch.—The pitch is the distance in inches or millimetres measured along a line parallel to the axis of the screw between the point where it cuts any thread of the screw and the point at which it next meets the corresponding part of the same thread (fig. 6). *The reciprocal of the pitch* measures the number of turns per inch or millimetre, as the case may be.

RECOMMENDATIONS.

Form of Thread.

1. The Association recommend that the Whitworth form of thread, as defined in clause 2, be adopted on all screws of $\frac{7}{32}$ in. diameter and above, having British Standard Fine Pitches.

Definition of Whitworth Form of Thread.

2. The following defines the Whitworth thread :—

The *Whitworth Form of Thread* is one in which the angle between the flanks, measured in the axial plane, is 55° ; one-sixth of the sharp triangle is truncated at top and bottom, the threads being rounded equally at crests and roots to a radius which is therefore 0·137329 times the pitch ; the depth of the thread is 0·640327 times the pitch.

TOLERANCES.

—	Full Diameter.	Effective Diameter.	Core Diameter.
Bolt	$3\times\cdot01\sqrt{p}$	$2\times\cdot01\sqrt{p}$	$4\times\cdot01\sqrt{p}$
Nut	$4\times\cdot01\sqrt{p}$	$2\times\cdot01\sqrt{p}$	$3\times\cdot01\sqrt{p}$

The corresponding tolerances on grade and play are :—

$$\text{Grade}=4\times\cdot01\sqrt{p}\,;\quad \text{Play}=2\times\cdot01\sqrt{p}.$$

In addition, a uniform allowance of 2 thousandths of an inch has been made throughout between the maximum bolt and the minimum nut.

For much work the above tolerances are too large. A second series of tables have therefore been formed by halving the tolerances everywhere. The Association recommend that threads made in accordance with these dimensions be known as ' British Standard Fine Threads (Close Fits).'

The basis of calculation of these tolerances is given below.

—	Full Diameter.	Effective Diameter.	Core Diameter.
Bolt	$1\cdot5\times\cdot01\sqrt{p}$	$\cdot01\sqrt{p}$	$2\times\cdot01\sqrt{p}$
Nut	$2\times\cdot01\sqrt{p}$	$\cdot01\sqrt{p}$	$1\cdot5\times\cdot01\sqrt{p}$

The corresponding tolerances and allowance are :—

$$\text{Grade tolerance}=2\times\cdot01\sqrt{p}\,;\quad \text{play tolerance}=\cdot01\sqrt{p}\,;\quad \text{allowance}=0\cdot002\text{ in.}$$

The pitches given in the following table are based on the following formulæ :—

For sizes up to and including screw threads of 1 inch diameter, $P=\frac{\sqrt[3]{d^2}}{10}$.

For sizes above 1 inch diameter, up to and including screw threads of 6 ins. diameter, $P=\frac{\sqrt[3]{d^4}}{10}$

$$\text{Pitch}=\frac{1}{\text{No. of threads per inch}}\,;\ \text{depth of thread}=0\cdot640327\times\text{pitch}\,;$$

$$\text{Rounding at crest and root}=0\cdot137329\times\text{pitch}.$$

British Standard Brass Thread.

This is a pipe thread system adopted for thin brass tubing, gas burner fittings, and general brass work; it has a Whitworth thread of a constant pitch of $\frac{1}{36}$-in., or 26 threads per inch.

Comparison of U.S. Standard and Whitworth Screw Threads.

The difference in form that exists between the Whitworth and the U.S. standard screw thread is shown in fig. 7. The comparison is based upon a screw with 1 thread per inch. Clearances and interferences for the two forms of threads having any other pitch may therefore be obtained by dividing the respective values given in the diagram by the number of threads per inch under consideration.

In order to fit a U.S. standard screw into a Whitworth tapped hole or nut, round the outside corners of the screw and change the outline of the thread below the pitch line by slightly filing the flanks. These changes are indicated in the figure by the sectional areas. If it is desired to fit a Whitworth screw into a U.S. standard tapped hole or nut, drill out the hole or nut, using a drill which is larger than the tap drill required for an equal size U.S. standard tap, as shown by

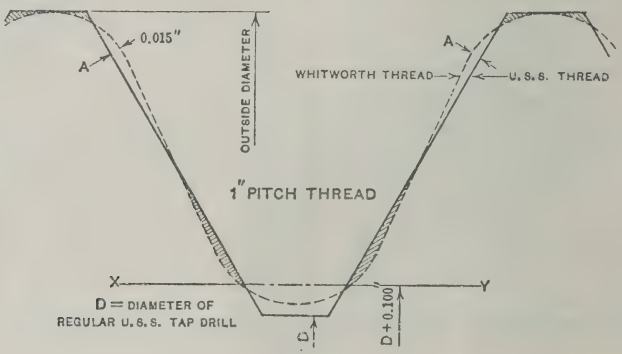

FIG. 7.

the line XY in the diagram. For 1 thread per inch, this increase in diameter of the tap drill will be 0·100 inch, and for other numbers of threads the amount of increase will be found by dividing 0·100 inch by the number of threads per inch. Thus, for 10 threads per inch, 0·100 ÷ 10 = 0·010 inch. The flanks of the Whitworth thread above the pitch line are then filed slightly as indicated at A in the illustration.

The methods mentioned are recommended only for fastening screws and ordinary threaded parts, and should not be employed where accurate threads are required.

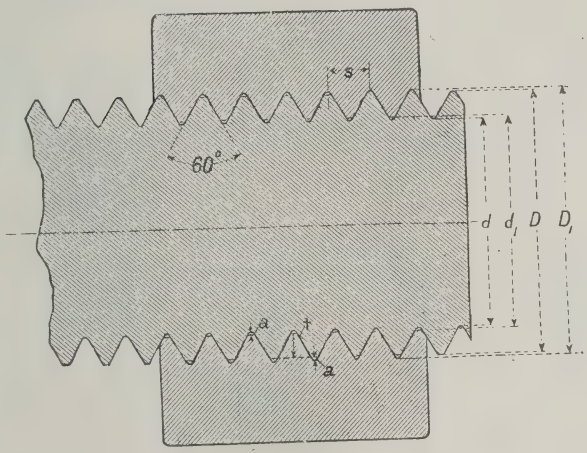
INTERNATIONAL SYSTEM OF METRICAL SCREW THREADS.



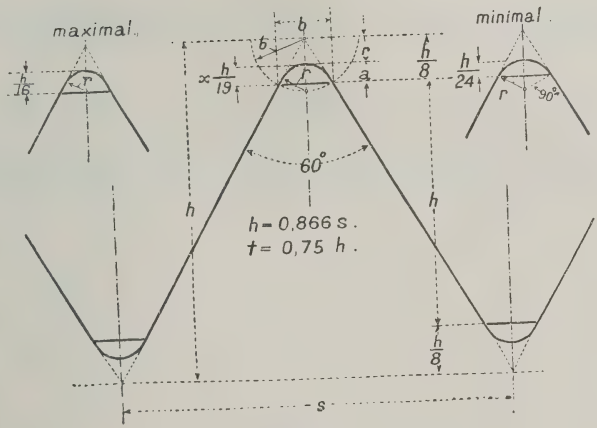


FIG. 8.

Wood Screws.

(Sometimes termed 'Screw Nails.')

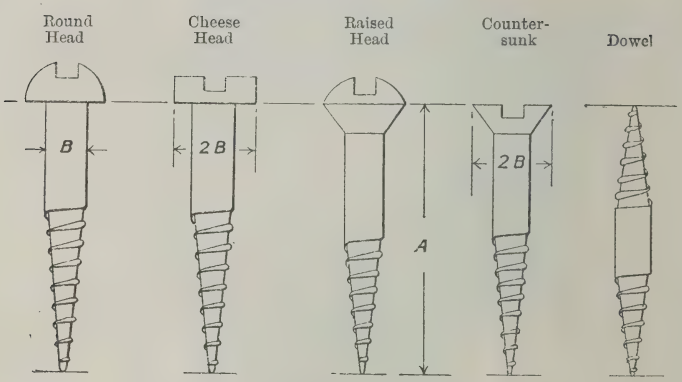

FIG. 9.

Wood screws are measured, as regards length (A), from the point to the portion normally flush with the surface of the material into which they are driven. Dowel screws are measured from point to point.

The number (size or thickness) (B) refers to the diameter of the shank or neck, and for Nettlefold's manufacture is as follows :—

Number.	Diameter.	Number.	Diameter.	Number.	Diameter.	Number.	Diameter.
	In.		In.		In.		In.
1	·066	9	·178	17	·290	25	·402
2	·080	10	·192	18	·304	26	·416
3	·094	11	·206	19	·318	27	·430
4	·108	12	·220	20	·332	28	·444
5	·122	13	·234	21	·346	29	·458
6	·136	14	·248	22	·360	30	·472
7	·150	15	·262	23	·374	31	·486
8	·164	16	·276	24	·388	32	·500

Formula for ascertaining diameter of screw :—

(·014 × No.) + ·052 in. = diameter.

Example :—(·014 × 16) + ·052 in. = ·224 + ·052 = ·276 diameter of No. 16.

The diameter of the head may be taken as twice the thickness of the neck.

Numerous lengths are obtainable in each size from ¼ in. in the smaller sizes to 9 ins. in No. 32.

Larger sizes are made to order but not gauged, and most sizes are obtainable in iron or brass.

NOTE ON WOOD SCREWS.

Wood screws may be put into the hardest of wood by the following process: A screw of the same size to be used is ground down to the form of a half-round bit. A hole, equal in diameter to the size of the screw at the bottom of the thread, is drilled into the wood, and the half-round tap is screwed in. This cuts a good thread, into which the screw may easily be screwed. Before introducing the screw, give it a good greasing with tallow, so that no binding can take place.

Screw Heads.

BRITISH STANDARD HEADS FOR SMALL SCREWS.*

(No. 57—1920.) (*Abstract.*)

For all classes of head the diameter to be 1·75 times the full diameter of the thread.

The width of saw-cuts to be according to the formula,

$$S = \cdot 2\ D + \cdot 1m,$$

where

S = width of saw-cut, and D = full diameter of the thread in millimetres.

The standard depth of saw-cut to equal one-half the total depth of the head in all cases, such depth being measured at the centre of the head.

NOTES ON TABLE.

Columns 1 and 2 of the table give the nominal bore of the tube and the full diameter of the screw in the coupler for use with that tube. The diameter of this screw has been chosen, in all cases, so that the coupler can be screwed by hand on to the tube, leaving from four to eight threads exposed.

The Association have preserved the Old Whitworth Standards as far as possible in the simplified dimensions for screwing sizes on tubes up to $2\frac{1}{4}$ ins. nominal bore. The Association have been guided in fixing the gauge diameters of the larger screwing sizes by the advantages of making the outside diameters of the tubes even quarters of inches.

* By permission of the British Engineering Standards Association.

Bolts and Nuts.

According to the Whitworth system of standard sizes of bolts and nuts, the thickness of the bolt-head is seven-eighths of the diameter, and the nut is equal to the diameter.

In the Sellers' (American) system the heads and nuts are hexagonal, the thickness of the heads and of the nuts being equal to 1 diameter minus one-sixteenth inch. The breadth across the flats is equal to $1\frac{1}{2}$ diameters plus one-sixteenth inch.

† The figures in this column represent the maximum width across the corners correct to two decimal places. The figures in italics are those for *black* nuts.

A chamfer of 30° from the face should be adopted on all bright nuts and bolt-heads. The interior diameter of the chamfer circle should not be appreciably less than the width across the flats.

British Standard Specification for Black, Iron and Steel, Cup and Countersunk Bolt-Heads, Nuts and Washers.

(See No. 325, 1928.)

T = D; A = $\frac{D}{2}$; B = $\frac{1}{8}$ in.

Nut Locking.

In the common locking arrangement, in which a thick and thin nut are employed, the thin nut should have a thickness approximately equal to two-thirds that of the standard nut.

LIST OF SPLIT PINS AND BOLT-END LENGTHS FOR NUT LOCKING.

To Lock a Nut.

(1).

In the absence of any of the regular nut-locking devices the work can still be done with an ordinary nut and washer. The stud or bolt used is first filed flat on one side at A, fig. 14, to

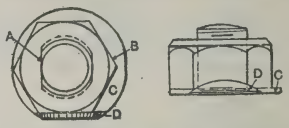

FIG. 14.

the depth of the threads. Next, the washer is given a few taps on one edge to elongate the hole, so that it will not turn when on the bolt. The nut B and washer C are then assembled in the usual manner, and when tightened up a chisel is inserted beneath the washer and the edge turned up at D, and tightened close to the side of the nut by hammering

This is an improvised method, but it acts just as well as the regular locking devices.

(*H. Moore*, '*The Mechanical World*,' *June* 22, 1923.)

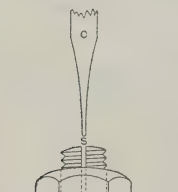

FIG. 15.

(2).

A slot S (fig. 15) is cut in the bolt with a hack-saw, and when the nut is tightly screwed home a cold chisel wedge C, whose width is less than the diameter of the bolt, is driven into the slot S (and then withdrawn) so as to spread out the end of the bolt, thus preventing the nut from unscrewing.

A serrated steel wedge can be driven into the slot if the nut is not required to be unscrewed again. (*H. R. Kempe.*)

* By permission of the British Engineering Standards Association.

Keys and Keyways.

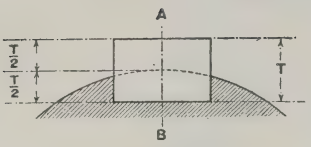

FIG. 18.

BRITISH STANDARD KEYS, KEY BARS, AND KEYWAYS.*

(No. 46—1909.) (*Abstract.*)

The keyway shall be cut in the shaft to a depth equal to one-half the thickness of the standard key it is intended to receive, and this depth shall be measured at the centre line (A–B) of the keyway.

For steam pipes allow 2½ inches per 100 feet for expansion.

British Standard Pipe Flanges.

(No. 10—Part 1—1928.)

Relates to Pipe Flanges (for Land Use) for Gas Pipes up to 30 lbs. pressure per square inch, and Water Pipes up to 175 lbs. pressure per square inch.

(No. 10—Part 2—1926.) (*Abstract.*)*

Table D.—For Working Steam Pressures up to 50 lbs. per sq. in.

Nominal Pipe Size.	Diameter of Flange.	Diameter of Bolt Circle.	Number of Bolts.	Diameter of Bolts.	Thickness of Flanges.

TAPPING.

It is a common occurrence for a tap to break when tapping hard metal. If the tap is ground away on the point, so that the first five or six threads are gradually bevelled, the risk of breakage may be largely avoided. The effect of grinding the end of the tap is to break up the chips into smaller pieces, and thus prevent clogging the threads of the tap. This will be found to be especially advantageous in tapping very hard rolled steel.

An easy rule for approximating tap-drill sizes is to deduct 1½ times the pitch from the outside diameter of the tap. In the case of a ⅜-in. tap, 16-pitch thread, for instance, 1½ times 1/16 = 3/32, and 3/8 − 3/32 = 9/32 = the diameter of the drill required for a ⅜-in. tap.

TAPPING LUBRICANTS.

Copper is tapped best with two-flute taps, using milk as a lubricant. Paraffin is well known to be the most suitable oil for use on aluminium, but is sometimes ruled out on account of its expense. Both the above pay when quantities of work merit the trouble occasioned by the adoption of a new lubricant. Paraffin must never be employed with ferrous metals—it tears badly.

CORRECT TAP GRINDING.

Grinding a tap consists usually of grinding the taper at the end of the tap, and the clearance back of the cutting edge thus formed. This taper may be long, as in nut taps; short, as in plug taps; or almost none, as in bottoming taps. The principle remains the same in each case. What is required is that each flute shall have exactly the same taper, just enough clearance so that it will cut freely, and not enough to needlessly weaken the cutting edge.

Prior to the advent of tap-grinding machinery nearly all taps were ground by hand, with a resultant lack of uniformity in taper and clearance. Fig. 29 shows a section of a four-flute tap with each flute ground differently in the matter of clearance or backing off. The flute A, at the left, is ground with a straight-line clearance just sufficient to have the heel of the flute actually clear and not drag. This calls for an angle of 15°, as indicated, and results in a weak cutting edge, but the strongest possible with a straight-line clearance at the heel.

The flute B, at the top, shows a 15° convex clearance. A glance shows this to be excessive. Flute C, at the right, shows a straight-line clearance of 5°, and nearly half of the flute at the back is not cleared at all, leaving the tap to ride on that portion and keep the front of the flute from cutting. Flute D, at the bottom, shows a perfect grind for ordinary work. It is a 5° convex

clearance, and shows that with this small but sufficient clearance angle at the cutting edge, the back is perfectly cleared.

In addition to the correct clearance of taps, a uniform angle of taper for all flutes is necessary. The results of different tapers obtained by hand-grinding are indicated in fig. 29. Even a slight variation from the uniform taper angle means power wasted and taps broken. As the blunt angle flute strikes the side of a drilled hole, it throws the cutting end of the tap off centre and imparts to it a wabbling motion. This means a tapped hole that is oversized, allowing the screw to fit loosely. Tap A is correctly ground and will tap a hole true to size, properly located and

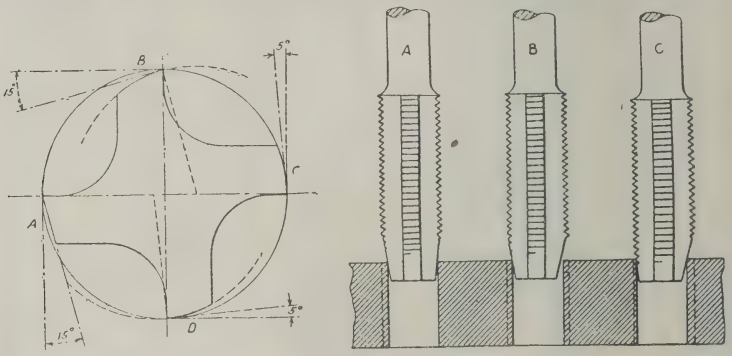

FIG. 29.

with smooth, accurately shaped threads. Tap B is ground with one flute at a more blunt angle than the other. This blunt flute is shown just as it strikes the drilled hole. Tap C shows a similar tap after it has been crowded over. The condition developed is readily seen.

(*' Railway Mechanical Engineer.'*)

THE "GUN" TAP.

A method of grinding a tap to give a cutting action similar to that of a turning tool is shown in fig. 30, which shows a ' Gun ' tap made by the Greenfield Tap & Die Corporation of America. The makers claim that the slope B of the face of the leading cutting edges (which are slightly hook-shaped, the edge being ground to give a negative rake) at A curls and projects the chips forward in an axial direction in front of the tap as tapping proceeds, the form of the chips, in steel, being spiral and more or less continuous. In this way the vicinity of the cutting operation at each flute is

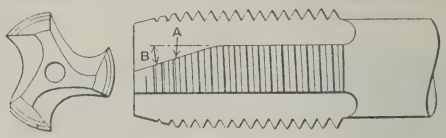

FIG. 30.

kept clear of swarf and the tap cuts freely, even through a long hole. The tap does not have to be backed out of long holes to clear a collection of chips from the flutes.

It is stated that the cutting pressure necessary with the ' Gun ' tap is 50 to 60 per cent. less than with an ordinary tap for the same size of thread. In deep holes the ' Gun ' tap has cut a full thread over four diameters long at a cutting pressure of 300 lbs., whereas an ordinary tap pulled up after tapping a full thread for a length of two diameters, the load being then 1,100 lbs., and stalling the machine.

Pipe Thread Tap Heads.

The Sheffield Small Tool Manufacturers have adopted the following list of sizes for the squares of pipe thread taps:—

No. of □.	Size of □ Inches. Fraction.	Size of □ Inches. Decimal.	Whitworth Thread Taps. Inches.	International Thread Taps. Millimetres.	Gas Tap. Inches.
0	$\frac{7}{64}$	·109	$\frac{1}{8}$	3 to $3\frac{1}{2}$	—
1	$\frac{9}{64}$	·140	$\frac{5}{32}$	4 to $4\frac{1}{2}$	—
2	$\frac{5}{32}$	·156	$\frac{3}{16}$	5	—
3	$\frac{13}{64}$	·203	$\frac{1}{4}$	6 to 7	—
4	$\frac{15}{64}$	·234	$\frac{5}{16}$ and $\frac{3}{8}$	8 to 10	$\frac{1}{8}$
5	$\frac{9}{32}$	·281	$\frac{7}{16}$	11 to 12	—
6	$\frac{5}{16}$	·312	$\frac{1}{2}$ and $\frac{9}{16}$	13 to 14	$\frac{1}{4}$
7	$\frac{25}{64}$	·390	$\frac{5}{8}$ and $\frac{11}{16}$	15 to 17	$\frac{3}{8}$
8	$\frac{29}{64}$	·453	$\frac{3}{4}$ and $\frac{13}{16}$	18 to 21	$\frac{1}{2}$
9	$\frac{35}{64}$	·546	$\frac{7}{8}$ and $\frac{15}{16}$	22 to 23	—
10	$\frac{41}{64}$	·640	1	24 to 26	$\frac{5}{8}$ and $\frac{3}{4}$
11	$\frac{23}{32}$	·718	$1\frac{1}{8}$	27 to 30	—
12	$\frac{13}{16}$	·812	$1\frac{1}{4}$	31 to 33	$\frac{7}{8}$ and 1
13	$\frac{27}{32}$	·843	$1\frac{3}{8}$	34 to 36	—
14	$\frac{29}{32}$	·906	$1\frac{1}{2}$	37 to 41	$1\frac{1}{4}$
15	$1\frac{5}{64}$	1·078	$1\frac{5}{8}$ and $1\frac{3}{4}$	42 to 46	$1\frac{1}{2}$ and $1\frac{3}{4}$
16	$1\frac{11}{64}$	1·203	$1\frac{7}{8}$ and 2	47 to 52	—
17	$1\frac{3}{8}$	1·375	$2\frac{1}{8}$ and $2\frac{1}{4}$	54 to 58	2 and $2\frac{1}{4}$
18	$1\frac{1}{2}$	1·500	$2\frac{3}{8}$ and $2\frac{1}{2}$	60 to 64	—
19	$1\frac{5}{8}$	1·625	$2\frac{5}{8}$ and $2\frac{3}{4}$	66 to 70	—
20	$1\frac{3}{4}$	1·750	$2\frac{7}{8}$ and 3	72 to 76	$2\frac{1}{2}$ to 3

Intermediate diameters have same squares as sizes below.

The heads of fluted hand reamers have same size squares as Whitworth taps and International thread taps, respectively.

The sizes of squares are stated in fractions and in decimals of inches, to facilitate measurement with either the mechanics' rule or the micrometer calliper.

No. of □ may be quoted when ordering tap wrenches.

Keeping Bolts in Place in Open-slotted Tables.

When bolts have to be used for repeat work in drilling machine or other open-slot types of tables, the flopping about and dropping of these bolts becomes a time-wasting nuisance. Fig. 32 shows two methods of holding them firmly in position, so that work can be removed

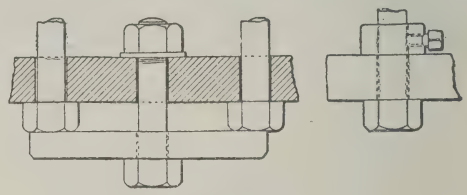

Fig. 32.

and a fresh piece substituted with the minimum of inconvenience. In the one case a clamp is suspended from a bolt and drawn up against the heads; in the other a loose collar is slipped down the bolt and tightened with a set-screw, an easier way than troubling to thread the bolt right down and putting a nut on. FIG. 34.

Washer Removably Attached to Screw.

There are cases where it is advisable to have a washer that cannot drop from its screw, and yet where it is impossible or impracticable to press or otherwise rigidly fasten it in place under the screw head, because it would be in the way of removal. The advantage is often considerable, for it is out of the question to lose the washer. Anyone who as ever dropped a washer into the working parts of some complicated machine, or lost it when it was needed in a hurry, will know how much the dropping of a washer may mean.

Fig. 35 shows a washer that cannot possibly drop off its screw, yet can be easily removed from the screw whenever desired. The arrangement can be applied to any screw and washer so long as they are still soft. The shank of the screw under the head, and the inner face of the washer, are each provided with a V-groove. Into the groove in the washer is sprung an oval-shaped piano-wire ring, so made that while it firmly seats in the washer, it will pinch the sides of the groove in the screw shank. The dimensions of the groove in the washer and of the wire must be such as will allow the washer with the ring in place to be slid over the shank without difficulty. The groove in the screw should be a slight distance away from the head, as shown, so as to make sure that the ring will always seat on the screw shank.

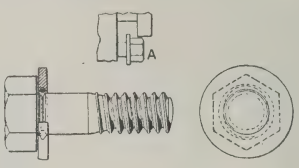

FIG. 35.

Since the depth of the groove in the screw is about the same as that of the thread, the strength of the screw is not diminished, so that no disadvantage of any kind is incurred to offset any part of the advantage gained.

At A is shown one out of many cases where an overhanging part would not permit the use of a pressed-on washer, but where the removable washer, while always in place, is never in the way. As soon as the screw has been loosened a few turns the washer is slid on the shank. From there on, as the screw is turned, the washer will either jump over successive threads or the threads will turn through it and the washer will be left on the threaded end when the screw is out.

(*'American Machinist.'*)

Rivet for Aircraft Construction and Other Purposes.

This rivet, the invention of Lieutenant J. W. Iseman, was designed for use in Duralumin construction work on airships in positions where it is difficult to hammer at one end and support the other, but it is also adaptable for other purposes, and is a very ingenious arrangement.

The rivet is shown in fig. 36 in position both before and after riveting. A hole ending in a conical point is drilled through the head of the rivet in the direction of the axis, as shown at A.

The base of the cone starts at the end of the nominal grip length of the rivet, this being equal to the thickness of the riveted plates. The end of the rivet is slotted up to the grip with two slots at right angles.

A pin of the same diameter as the hole and ending in a similar cone is tapped into the rivet until the end is flush with the head, as shown at B. This pin causes the slotted end to spread out as the straight side of the pin travels along the side of the cone. When the pin is home, the sides of the cone are parallel to the axis of the rivet as at B.

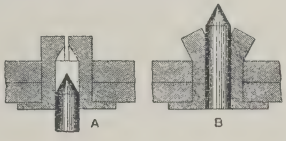

FIG. 36.

It is found that friction and binding between the rivet and the pin are quite sufficient to hold the latter in place.

Tests of these rivets have shown that with an outside diameter of 0·127 in. and a pin 0·053 in. in diameter, a shear strength of 450 lb., or 35,500 lb. per square inch, can be reached.

SECTION XXIII

THE ATMOSPHERE — WIND — AIR RESISTANCE — WINDMILLS—TRANSMISSION OF POWER BY COMPRESSED AIR—AIR COMPRESSORS—PNEUMATIC DESPATCH TUBES

(pp. 1181–1206)

(With Contributions by Edward Butler, M.I.Mech.E., and R. A. Sturgeon, Assoc.M.Inst.C.E.)

SECTION XXIII

THE ATMOSPHERE—WIND—AIR-RESISTANCE—WINDMILLS—AIR COMPRESSION—AIR COMPRESSORS—PNEUMATIC DESPATCH TUBES.

The Atmosphere.

Air consists, by volume, of oxygen 20·84 parts, of nitrogen, 79·16 parts; and by weight, of oxygen 23·15 parts, and of nitrogen 76·85 parts. Also 0·03 to 0·04 per cent., by volume, of carbonic acid.*

One cubic foot of ordinary dry air at normal pressure, temp. 62° F., weighs 532·5 grains (saturated 529 grains); or 1 lb. of air contains 13·146 cubic feet.

Dry air is 819 times lighter than water. Aqueous vapour, 1·4 per cent. by volume.

At 60° a cubic foot of saturated air contains 0·00083 lb. of moisture. This increases to 0·00285 lb. at 100° and 0·030 lb. at 200°. These are exactly the same as the weight of a cubic foot of saturated steam at the given temperatures.

The viscosity of air in C.G.S. units is 1·48 at 15° C. (59° F.) and 1·49 at 16·5° C. (61·7° F.).

The mean weight of a column of air 1 inch square and 45 miles high is 15 lbs.

Density of air $= \left(\frac{1}{4}\right)^{\frac{h}{6\cdot8}} = (0\cdot8156)^{h}$; Pressure of air, $p = 14\cdot7\,(0\cdot8156)^{h}$ lbs. per sq. in.

$$h = \frac{\log.\frac{p}{14\cdot7}}{-0\cdot0885228}$$

where h = height in miles above surface of earth.

At 6·8 miles above the surface of the earth the air is 4 times lighter than at the earth's surface; at 13·6 miles, 16 times; at 20·4 miles, 64 times. Total weight of atmosphere, 5,300 billion tons.

According to a writer in *Nature*, the result of experiments made with forty balloons (sent up in Great Britain) has been that the isothermal layer was reached more than thirty times. Its average height was 35,000 ft. (10·7 kiloms.); it is rather higher with a high barometer. The mean temperature found was — 53·6° F. (— 77° C.), considerably higher than the Continental mean. The extremes observed in England were — 22° F., near Ditcham Park, Hants, on July 24, and — 73° F., near Oxford, on September 12, 1907. On the same day, November 11, 1907, the temperature was — 42° F. at Ditcham at 36,000 ft. altitude, — 58° F. in Oxfordshire at 38,500 ft., and — 74° F. near Manchester at 37,000 ft. The existence of an isothermal layer in equilibrium in which the fall of temperature suddenly stops, and yet in which such great differences of temperature occur at spots not very far from one another, is difficult to understand, especially considering the low atmospheric pressure at these heights.

To consume 1 lb. of coal requires 11½ lbs., or 150 cubic feet, of air to combine with it.

The work stored up in 1 cu. ft. of air at atmospheric pressure, i.e. the work it would do if allowed to expand into an absolute vacuum = 5,188 ft. lbs.

The expansion of air, like all other elastic fluids, is uniform at all temperatures.

* Air contains 15 parts of 'neon' and 5 parts of 'helium,' in one million volumes (*Dewar*)

If h = height of barometrical column of mercury ; K = number of square inches in section of tube ; 13,568 ozs., or 848 lbs. = weight of cubic foot of mercury at mean temperature : p = number of pounds pressure of air on square inch of surface ; then

Pressure of atmosphere on K sq. ins. $= p \times K$. Weight of column of mercury $= \frac{Kh}{1728} \times 848$.

But column of mercury balances the pressure of the atmosphere ; therefore

$$p \times K = \frac{Kh}{1728} \times 848, \qquad \text{or,} \qquad p = \frac{848}{1728} \times h = \frac{53h}{108} = \frac{h}{2} \text{ very nearly.}$$

Hence it appears that *the pressure of the atmosphere in pounds per square inch is very nearly equal to half the column of mercury in the barometer-tube in inches.*

The column of mercury in the barometer in this country varies from 28 to 31 ins. ; therefore the mean column is 29·5 ins. ; and by the foregoing result the mean pressure of the atmosphere will be about 14·7 lbs. per square inch.

Rankine assumes a standard English atmosphere to be 14·704 lbs. per square inch in the latitude of London, or equal to a mercury column 29·922 ins. high at 32° F., which = 30 ins. at 57·8° F.

The metrical atmosphere, 760 mm. (29·922 ins.), at 0° C. (32° F.) = 1·0333 kilograms per square cm., or 14·6967 lbs. per square inch, at Paris = 14·686 lbs. at New York.

To find the barometric height, H, at any latitude, l,

$$H = 760 \times \frac{(1 + 0{\cdot}00531 \sin^2 48° 50')}{(1 + 0{\cdot}00531 \sin^2 l)} \text{ mm.,}$$

where 48° 50′ is the latitude of Paris.

The altitude or head of the atmosphere at uniform density will be that of a column of water 33·95 ft. high divided by the specific gravity of air (·0012046), or 28,183 ft. The velocity due at the foot of this head will be : $V = 8{\cdot}02 \sqrt{28183} = 1346{\cdot}4$ ft. per second, the velocity at which the air will pass into a vacuum. The motions and effects of gases by the force of gravity are precisely the same as those of liquids. Under like conditions a conduit will discharge 30·55 times more air than water.

Liquid Air.

Liquid air is produced by passing highly compressed air through a counter flow heat exchanger followed by an expansion device. On expansion the air is cooled and the cold air thus produced passes back through the heat exchanger, so cooling the incoming compressed air. The cooling is thus self-intensive, and finally results in liquefaction of part of the expanded air. The unliquefied part escapes through the heat exchanger and so keeps up the cooling effect. The expansion may take place through a nozzle, or in an expansion engine with the output of external work. The initial pressure used varies in different systems from about 45 atms. to 200 atms. About 8 to 12 per cent. of the air supply is liquefied, and the power required is from 1 to 2 h.p. hrs. per lb. of liquid produced, according to size and type of plant employed.

The critical temperature of air, above which it cannot be liquefied, is −140° C., and the corresponding critical pressure is 39 atms. The boiling point at atmospheric pressure is about −190° C., and the latent heat of evaporation about 50 calories. The specific gravity of the liquid is about 0·88.

If liquid air (21 per cent. O_2) is allowed to evaporate quietly it gives off a vapour containing about 7 per cent. O_2 owing to the fact that nitrogen boils at a temperature 12° C. lower than that of oxygen. The remaining liquid consequently becomes richer in oxygen as evaporation proceeds, and the boiling point rises until finally a temperature of −184° C. is reached (the boiling point of liquid oxygen).

The chief use of liquid air is in the process of obtaining oxygen and nitrogen from the atmosphere by means of liquefaction and distillation. Argon and neon are also obtained in the same way by additions to the ordinary oxygen or nitrogen apparatus.

Liquid air as such is used industrially for obtaining very low temperatures. One application is the freezing of mercury vapour during the evacuation of radio valves where the evacuation is performed by mercury vapour pumps. The mercury vapour is prevented from reaching the valves by the insertion of a liquid air trap in the pump circuit. A somewhat kindred use is the charcoal pump, in which specially prepared charcoal is cooled in liquid air. When so cooled the charcoal absorbs a large volume of air, and so can produce a higher vacuum than is obtainable by any other known method.

Liquid oxygen is used in breathing apparatus either for mine rescue work or for high altitude flying. It is also used in conjunction with special cartridges as an explosive for use in quarries

and mines. The chief advantages of this explosive lie in the facts (1) that it can generally be manufactured on the spot, as suitable material for the cartridges can be obtained almost anywhere, and (2) that neither the cartridge nor the liquid oxygen is in itself explosive. The actual soaking of the cartridge which renders it explosive is only performed immediately before insertion into the bore hole.

Velocity of Air.

When air passes into an air of less density, the velocity of its passage is measured by the difference of the densities of the two.

H and h = densities of the air in inches of mercury ; t = temperature (F.°) at the time of passage ; and V = velocity of air in feet per second.

$$V = 1347{\cdot}4\sqrt{\frac{H-h}{h}\left(1+0{\cdot}002088t\right)}.$$

Pressure against a Plane Surface moved through the Air.

P = pressure against plane. a = area of plane, in square feet. v = velocity, in feet per second. v_1 = velocity in miles per hour.

$$P = {\cdot}00142av^2 \text{ lbs.}^* \qquad P = {\cdot}0029av_1^2 \text{ lbs.}^*$$

$P = ({\cdot}003 + {\cdot}00004q)\,av_1^2$ lbs.,† where q = ratio of sides of rectangular plate.

The quantity ·003 decreases as v_1 increases, being ·0029 for 90 miles, and ·0032 for 0 to 25 miles.

Horse-power required to move a Plane Surface against the Air.

H.P. = horse-power. a = area of plane, in square feet. v = velocity, in feet per minute.

$$\text{H.P.} = {\cdot}000{,}000{,}000{,}010{,}6av^3.$$

TABLE SHOWING HORSE-POWER CONSUMED IN MOVING A PLANE SURFACE AGAINST THE AIR.

Speed in		H.P. per Sq.Ft. of Effective Surface.	Speed in		H.P. per Sq. Ft. of Effective Surface.
Miles per Hour.	Feet per Min.		Miles per Hour.	Feet per Min.	
10	880	0·00722	50	4,400	0·903
15	1,320	0·0244	75	6,600	3·05
20	1,760	0·0514	100	8,800	7·23
25	2,200	0·110	150	13,200	24·4
30	2,640	0·195	200	17,600	57·8

As a result of tests, M. Eiffel found that, for velocities of from 60 ft. to 130 ft. per second, the resistance offered by air to a moving surface is practically proportional to the square of the velocity, although the exponent increases slightly and gradually when velocities exceeding 100 ft. per second are employed. The resistance or pressure in pounds, P, is represented by the product KSV^2, where K is a constant depending on the size and shape of the surface tested ; S is the area of the surface in square feet, and V is the velocity in miles per hour. At ordinary temperatures and a barometric pressure of 760 mm., M. Eiffel found that the value of the coefficient K ranged from 0·00286 to 0·00327, the latter value being apparently a maximum attained only with large surfaces. Thus, for a circular surface of 1 sq. ft., the value of K was 0·00286, for a square surface of the same area 0·00295, and for an area of 10 sq. ft. 0·00323. He also found that the resistance of an inclined surface is practically the same as that of a normal one, when the perpendicular to the surface makes an angle less than 30° with the direction of motion. For greater angles the resistance proportionately decreases (zero at 90°). On pressure boards ranging from 25 sq. ft. to 100 sq. ft. in area, which were mounted at the top of a 50 ft. tower, Dr. T. E. Stanton found, from a large number of experiments, that the mean value of this constant was 0·0032.

Dr. Hutton deduced that the resistance of air varied as the square of the velocity nearly, and to an inclined surface as the 1·84 power of the sine × cosine.

The figure of a plane makes no appreciable difference in the resistance, but the convex surface of a hemisphere, with a surface double the base, has only half the resistance.

At high velocities the resistance becomes nearly a constant quantity.

The resistance of the air to a train of cars in a dead calm was found to be $\frac{1}{200}$ of their weight.

The velocity of a train of cars which gave a resistance of $\frac{1}{200}$ of the load with a fair wind was 34½ miles per hour, and only 27½ with an adverse wind.

* T. E. Stanton, National Physical Laboratory. † Hagen.

Flow of Air.

Weight of Air Passing Through a Nozzle.

The weight of air at atmospheric pressure passing through a properly-designed nozzle into any vacuum of not less than 8 lbs. may be calculated as follows (Leblanc) :—

W = lb. weight per hour ; A = area of nozzle neck in square inches ; T = atmospheric temperature in deg. Cent.

$$W = \frac{20330A}{\sqrt{T + 273}}$$

Air Friction.

Recent experiments on the flow of air through smooth sheet steel ducts varying in size from 12 ins. to 48 ins. in diameter, at velocities ranging from 1,000 ft. to 2,400 ft. per min., appear to show that the average value of the coefficient of friction is 0·0035.

Impulse of Wind.

V = velocity of wind. D = direct impulse in pounds on one square foot.

$D = V^2 \times \cdot00271$, where V is in miles per hour
$D = V^2 \times \cdot00312$, where V is in knots per hour } *

Model experiments carried out in a wind tunnel at Washington show that a wind blowing at 76 miles per hour produces a pressure of 22 lb. per sq. ft. on a tall building.

Wind Velocity by Robinson Anemometer.

If

v = velocity of anemometer cups in miles per hour ; V = velocity of wind in miles per hour ; then,

$$V = 2v + 4.$$

Instrument fails to record velocities below 4 miles per hour.

(*W. H. Dines*, 'Report of Astronomer Royal, 1921.')

* Recent researches have shown that the constants ·00271 and ·00312 are apparently too small by about 6 per cent.

WINDMILLS.

(Contributed by Edward Butler, M.I.Mech.E.)

The driving shaft of a windmill situated on level ground should, with a tower of moderate height, be tilted *upwards* at an angle of 6° to 8°. If on a low hill with the fall against the prevailing wind the shaft is better horizontal, but when situated on a steep hill the best result will be obtained by tilting the shaft *downwards* a few degrees.

The shaft should be mounted so that the driving-wheel faces the wind in either direction and at a height ranging from 20-25 ft. on high ground, and 50-70 ft. on low ground, and so that it is clear of buildings or trees.

The tower should, in ordinary circumstances, be of sufficient strength to hold up against a 40-mile storm with a wind pressure of 8 lbs. per sq. ft. On exposed elevations subject to wind velocities exceeding this, a windmill unless specially constructed is not suitable.

WIND ACTION.

Velocity per hour in miles.	Pressure per sq. ft. in lbs.	Description of Wind.	Action on Windmill.
5	0·125	Faint breeze . .	Will not drive.
8	0·33	Breeze . . .	Will start against light load.
10	0·5	Fresh breeze . .	Will run slowly.
15	1·125	Good wind . .	Will run steadily.
20	2·	Strong wind . .	Gives best service.
25	3·125	Very strong wind .	Maximum useful effect.
30	4·5	Gale . . .	Should be partly furled or held out of the wind.
40	8·	Storm . . .	Must be totally put out of action.
60	18·	Violent storm .	Not safe.
80	30·	Hurricane . .	„ „
100	50·	Tornado . . .	„ „

Power of Windwheels.

The total momentum of wind is,

$$\frac{0{\cdot}08}{32{\cdot}2} \times \text{area} \times \text{velocity}^2 = 0{\cdot}0025\ AV^2, \text{ approximately.}$$

The turning moment at starting, for each vane, equals

$$0{\cdot}002\ AV^2 \cos\theta r,$$

and when in motion is

$$0{\cdot}0015\ AV^2 \cos\theta r \text{ for moderate speed,}$$

the constant ·0015 decreasing to 0·0012 with increase of speed;

where A = area of vane; V = velocity of wind; θ = angle to the axis of rotation; r = mean radius; 0·08 is the mean weight of one cubic foot of air. Velocity in ft. per sec. is to miles per hour as 22 is to 15.

HORSE-POWER OF WINDWHEELS.

Shaft or b.h.p. of a 4-armed wheel with cloth sails

$$= \frac{v^3 r^2}{512477}\ (\textit{Rankine}), \quad \frac{4\ Av^3}{1145833}\ (\textit{Weisbach}).$$

The brake h.p. of a multi-vaned wheel

$$= \frac{0{\cdot}6 \times 0{\cdot}78\ (D^2 - d^2) \times V^3}{33000};$$

where,

A = area of one vane; D = total diameter of wheel; d = clearance diameter at centre; r = radius of sail tips; V = velocity in feet per second.

A windwheel (Dutch pattern) with four cloth sails, each 24 ft. in length and 6 ft. in breadth, will develop 4-5 b.h.p. in a 20-mile wind.

Windwheels with multiple vanes have a considerable advantage in starting with low velocity winds and in slow running.

The power of a windwheel is not so great as is popularly supposed. A 16 ft. wheel, for instance, with multiple cambered steel vanes, only develops about 1 b.h.p. in a 15-mile wind, and this is reduced to less than one-half in a 10-mile wind, although increased to nearly double in a 20-mile wind.

Construction.

According to windmill practice (old type) the wheel may have 4, 5, or 6 cloth sails of rectangular form, the length being equal to five times the breadth; but the total surface should not exceed one-third of the whole surface described by the radial arms carrying the sails. The angles of the cross bars for supporting the sails, which commence at one-seventh from the wheel centre, are usually 24°, 21°, 18°, 9°, 3°, from the plane of motion.

While more power can be gained by increasing the sail surface to more than one-half the wheel area, the difficulty is such with the old practice of using cloth sails that the sail area seldom exceeds one-third and is more often reduced to one-fourth.

The angles of the sails to the plane of motion, according to Smeaton, should be 20°, 19°, 18°, 16°, 12½°, 7°; and again, to Forrester, as 24°, 21°, 18°, 14°, 9°, 3°.

In multi-vane windwheels, the vanes—either oil-soaked wood slats, or cambered steel plates of light construction and galvanised—are carried by a series of 6-8 steel or wooden arms, fixed to a steel boss. The arms are braced to an extension of the wheel boss by tension rods. The vanes are fastened to two sets of cross-bars, connecting the arms together, in sections of 8 to 15, according to wheel diameter and angle to the plane of motion; this varies from 20° to 40°, but is generally 25° in flat or cambered vanes of uniform angle. The steeper the angle the narrower the vanes, to reduce whirl resistance. For direct connected pumps the angle is steeper than for geared down pumps. Steel vanes are cambered more for rigidity than for any increased driving efficiency. There is some advantage in forming the angle to suit the radius, but is not of such consequence as with wide cloth sails. What is of more importance is for the shaft to run in well lubricated roller bearings and for the turntable to move freely so that the wheel shall be held square to a light wind.

Power Control.

In windwheels with wide cloth sails, these are furled to suit either the load or the wind. In wheels with multiple vanes the usual practice is to fit a governor-vane on one side, at a right-angle to the wheel shaft, and for the tail-vane to be swivelled to the turntable, and to be held end-on either by a spring or a weight, or, better still, by a series of weights chained together. These weights should be proportioned for the governor-vane so as to pull the turntable, and the wheel with it, partly out of the wind as soon as the velocity increases 20-25 m.p.h., and to bring round the wheel edge-on to the wind in a storm.

Wind Pumps.

The popularity of wind-driven pumps is due to the introduction of the multiple-vaned wheel and to automatic governing, in combination with light easily-erected steel towers, the average power developed ranging from 1 to 6 shaft h.p., with a wind velocity of 15 m.p.h. (22 ft. per sec.), a 20-mile wind nearly doubling this power, and a 10-mile wind generating about half the power obtained by a 15-mile wind.

In ordinary practice the pumping capacity of a wind engine, as expressed in pounds of water raised per minute by pressure-head in feet, rarely exceeds from 25 to 35 per cent. of the wheel h.p., but is influenced by wheel diameter, the angle of the vanes, and the method of transmitting the power to the plunger.

In geared-down transmissions, the wheel-shaft pinion should be situated at the side of the pump wheel, and not above or below it. This disposition reduces friction and maintains correct alignment and mesh of the cogs.

Owing to the very inadequate fly-wheel effect of a windwheel, it works at considerable disadvantage in driving single-acting pumps direct, and only less so when geared down; double-acting, or better, 3-throw single-acting pumps, oppose a more equable torque, but are impracticable for small installations. For this reason a rack or mangle transmission is peculiarly applicable to a wind-driven pump, as shown in the higher duty and efficiency in the table, p. 1187.

The location of a wind pump is generally influenced more by the available water supply than from any consideration of available wind-power, the tower usually being constructed high enough—50 to 70 ft.—to clear all obstacles around for a distance of 300 to 400 ft. Under normal conditions eight hours' pumping only can generally be relied upon as a daily average; so that to make an installation successful a storage-tank or reservoir should be provided, the minimum capacity of which may with advantage equal from four to seven days' pumping, although a larger reserve is often allowed for.

AIR COMPRESSION.

RELATION BETWEEN PRESSURE AND VOLUME.

If

p = actual pressure of air in a container;
P = gauge ,, ,, ,,
v = volume of air at pressure p;

p_1 = actual pressure of air when compressed;
P_1 = gauge ,, ,, ,,
v_1 = volume of air when compressed;

then,

$$\frac{p}{p_1} = \frac{P + 14{\cdot}7}{P_1 + 14{\cdot}7} = \frac{v_1}{v},$$

the compressed air being *at the same temperature* as the air before compression—that is to say, if the heat due to the compression is allowed to become dissipated.

If the air is compressed from atmospheric pressure (i.e. if gauge pressure P = 0), then

$$\frac{14\cdot7}{P_1 + 14\cdot7} = \frac{v_1}{v},$$

or,

$$P_1 = 14\cdot7\frac{v - v_1}{v_1}, \quad \text{and} \quad v_1 = v\frac{14\cdot7}{P_1 + 14\cdot7}.$$

Example 1.—What gauge pressure (P_1) would be required to reduce 5 cub. ft. (v) of air at atmospheric pressure down to 3 cub. ft. (v_1), at the same temperature?

$$P_1 = 14\cdot7\,\frac{5-3}{3} = 9\cdot80 \text{ lbs.}$$

Example 2.—What volume (v_1) will 1 cub. ft. of air occupy when compressed to 30 lbs. gauge pressure (P_1), at the same temperature?

$$v_1 = 1\,\frac{14\cdot7}{30 + 14\cdot7} = 329 \text{ cub. ft.}$$

If the heat is not allowed to disappear when the air is compressed, then

$$\frac{14\cdot7}{P_1 + 14\cdot7} = \left(\frac{v_1}{v}\right)^{1\cdot408}$$

or,

$$P_1 = 14\cdot7\frac{v^{1\cdot408} - v_1{}^{1\cdot408}}{v_1{}^{1\cdot408}}, \quad \text{and} \quad v_1 = v\left(\frac{14\cdot7}{P_1 + 14\cdot7}\right)^{\cdot7102}$$

If $P_1 = 30$, as in the case of *Example* 2, then the value of v_1 instead of being ·329, will be

$$(\cdot329)^{\cdot7102} = \cdot454 \text{ cub. ft.}$$

Work and Horse-power in Compressed Air.

(1)

Work.

The effective work, W, stored up in 1 cu. ft. of compressed air (or the work required to compress the air) at a gauge pressure (pressure above atmosphere) of P_1 lbs. per sq. in. is

$$W = 352\cdot94\,(P_1 + 14\cdot7)\left(1 - \left(\frac{14\cdot7}{P_1 + 14\cdot7}\right)^{0\cdot29}\right) \text{ ft. lbs.}$$

Example.—1 cu. ft. of compressed air at a gauge pressure of 10 lbs. (the resulting heat not being allowed to disappear when the compression takes place) will contain:

$$352\cdot94 \times 24\cdot7\left(1 - \left(\frac{14\cdot7}{24\cdot7}\right)^{0\cdot29}\right) = 352\cdot94 \times 24\cdot7(1 - 0\cdot86028) = 1{,}218 \text{ ft. lbs. of}$$

effective work, *i.e.* the work it would do in expanding down to atmospheric pressure.

Horse-Power.

The H.P. required to produce 1 cu. ft. per min. of compressed air at P_1 lbs. pressure, is

$$W \div 33{,}000, \quad \text{or,} \quad H.P. = 0\cdot0107\,(P_1 + 14\cdot7)\left(1 - \left(\frac{14\cdot7}{P_1 + 14\cdot7}\right)^{0\cdot29}\right).$$

Example.—To produce 1,000 cu. ft. per min. of compressed air at 10 lbs. pressure would require

$$H.P. = 1{,}218 \div 33{,}000 \times 1{,}000 = 36\cdot9.$$

(2)

Work.

The effective work, w, stored up in 1 cu. ft. of air at atmospheric pressure when compressed to a gauge pressure of P_2 lbs. per sq. in., is

$$w = 352{\cdot}94 \times 14{\cdot}7 \left(\left(\frac{P_1 + 14{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 1 \right) = 5188{\cdot}2 \left(\left(\frac{P_1 + 14{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 1 \right) \text{ ft. lbs.}$$

Example.—1 cu. ft. of atmospheric air, when compressed to a gauge pressure of 10 lbs. (the resulting heat not being allowed to disappear when the compression takes place), will contain

$$5188{\cdot}2 \left(\left(\frac{24{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 1 \right) = 5188{\cdot}2 \quad 1{\cdot}1624 - 1) = 843 \text{ ft. lbs. of effective work.}$$

Horse-Power.

The H.P. required to compress 1 cu. ft. per min. of air at atmospheric pressure to P_1 lbs. gauge pressure, is

$$W \div 33{,}000, \quad \text{or,} \quad \text{H.P.} = 0{\cdot}157 \left(\left(\frac{P_1 + 14{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 1 \right).$$

Example.—To compress 1,000 cu. ft. per min. of atmospheric air to 10 lbs. gauge pressure would require

$$\text{H.P.} = 843 \div 33{,}000 \times 1{,}000 = 25{\cdot}6.$$

(3)

$$\frac{W}{w} = \left(\frac{P_1 + 14{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}7102}.$$

Example.—If $P_1 = 10$ lbs.,

$$\frac{W}{w} = \left(\frac{24{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}7102} = 1{\cdot}446.$$

INCREASE OF TEMPERATURE OF AIR BY COMPRESSION.

If air at atmospheric pressure and at a temperature $t_1°$ F. be compressed suddenly to a gauge pressure P_1, then the temperature will be raised to $t_2°$ F., where

$$t_2° = (459 + t_1°) \left(\frac{P_1 + 14{\cdot}7}{14{\cdot}7} \right)^{0{\cdot}29} - 459.$$

Example.—If air at 32° F. temperature ($t_1°$) be compressed to 10 lbs. gauge pressure (P_1), then temperature $t_2°$ of air will be raised to

$$t_2° = 491 \quad \frac{24{\cdot}7}{14{\cdot}7} \Big)^{0{\cdot}29} - 459 = 491 \times 1{\cdot}162 - 459 = 112° \text{ F}$$

PRESSURE OF AIR PRODUCED BY INCREASE OF TEMPERATURE.

If air at atmospheric pressure in a closed vessel and at $t_1°$ F. be raised to $t_2°$ F., then the gauge pressure, P_1, of the air will be

$$P_1 = 14{\cdot}7 \left(\frac{459 + t_2}{459 + t_1} \right)^{3{\cdot}45} - 14{\cdot}7.$$

Example.—If $t_1° = 32$, $t_2° = 112$, then $P_1 = 14{\cdot}7 \left(\frac{571}{491} \right)^{3{\cdot}45} - 14{\cdot}7 = 24{\cdot}7 - 14{\cdot}7 = 10$ lbs.

INCREASE OF VOLUME OF AIR BY INCREASE OF TEMPERATURE.

If a volume, V_1, of air at atmospheric pressure and at $t_1°$ F. be raised to $t_2°$ F., the air being allowed to expand freely, then the volume V_2 at $t_2°$ F. will be

$$V_2 = V_1 \frac{461 + t_2°}{461 + t_1°}.$$

Example.—If volume V_1 of air at 32° ($t_1°$) be 1,000, then volume V_2 at 525° ($t_2°$) will be:

$$V_2 = 1{,}000 \frac{461 + 525}{461 + 32} = 1{,}000 \times \frac{986}{493} = 2{,}000.$$

The following table gives the increase in volume from 32° F :—

INCREASE OF VOLUME OF AIR BY INCREASE OF TEMPERATURE FROM 32° F.

AIR COMPRESSORS.

The mechanical efficiency of air compressors is about 60 per cent. at 5 pounds per square inch, increasing to 80 per cent. at 40 pounds per square inch and above. It is quite usual for the best makes to attain an efficiency exceeding 90 per cent., but for general purposes it is wiser to assume the lower figure. In the case of machines of small output and low pressure, the efficiency is frequently below 50 per cent.

In providing a driving unit for an air compressor, the type of machine should be considered before fixing the size of the driver. Thus, the turning effort required by a single-acting, single-cylinder air compressor may vary considerably above and below the mean, and allowance must be made for this, particularly in the case of direct-coupled drives.

DESIGN OF AIR COMPRESSORS.

The best practice adopted in the design of air compressors is as follows :—The maximum terminal pressures are, for one stage, 80 lbs. to 100 lbs. per sq. in. ; two stages, 600 lbs. per sq. in. ; three stages, 1,500 lbs. per sq. in. ; four stages, 2,500 lbs. to 3,000 lbs. per sq. in. ; five stages, 4,500 lbs. per sq. in. ; and above 4,500 lbs. per sq. in., six or seven stages to 6,000 lbs. per sq. in., which is about the highest pressure for which an air compressor has been constructed. In the case of very small machines these pressures, for a given number of stages, are often exceeded in order to reduce complication. For example, machines have been constructed and work quite satisfactorily when compressing to 2,500 lbs. per sq. in. in two stages. The temperatures attained, however, make it necessary to carry out the cylinder lubrication by soapy water.

(*J. M. Ford, in a paper read before the Greenock Association of Shipbuilders and Engineers.*)

'BROTHERHOOD' AIR COMPRESSORS FOR MODERATE PRESSURES.

(*Peter Brotherhood, Ltd., Peterborough.*)

These compressors are made in a wide range of sizes, for small capacities of the single-acting trunk-piston type and for larger capacities of the double-acting type. The former are lubricated automatically, and the latter by forced lubrication.

BROTHERHOOD AIR COMPRESSOR

FIG. 1.—Details of Valves.

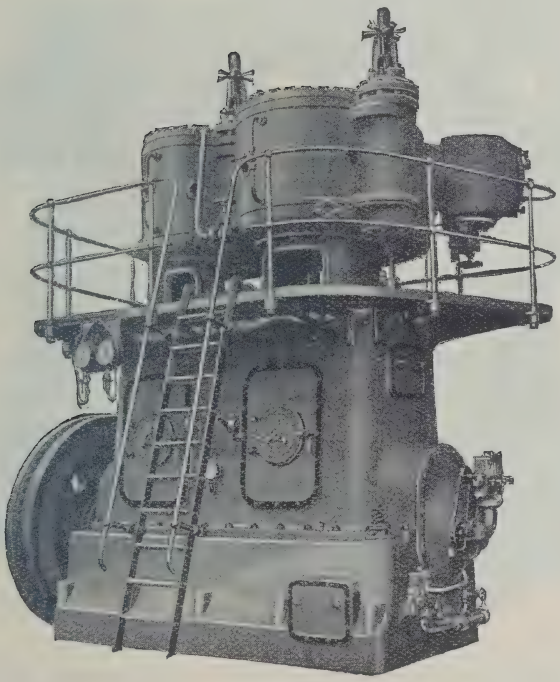

FIG. 2.

BROTHERHOOD AIR COMPRESSOR.

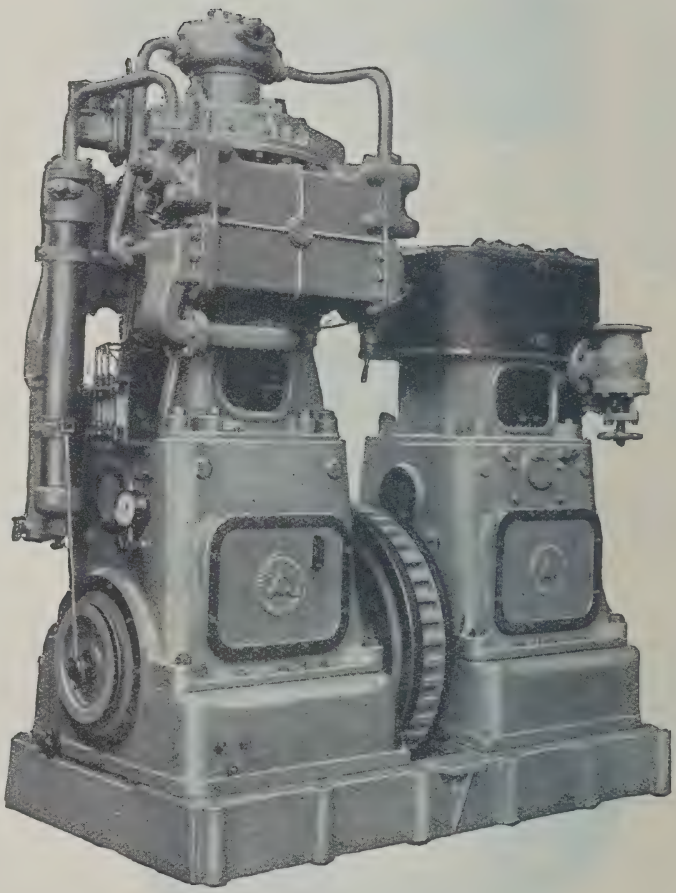

FIG. 3.

The single-acting types are designed for one or two stage, working up to a free air capacity of about 200 cu. ft. per minute, and are suitable for driving by belt, motor, or engine.

The double-acting types include single-line simple and tandem two-stage machines up to about 800 cu. ft. of free air per minute, and two-line simple and two-stage up to about 6,000 and 5,000 cu. ft., respectively.

The valves, which are illustrated on fig. 1, p. 1191, combine a large opening with very small moving mass, and will operate continuously at very high speeds.

The general construction of the double-acting types is shown on fig. 2, which illustrates a two-stage machine of 4,000 cu. ft. free air capacity.

The governing adopted varies according to the form of drive employed; for belt or motor drive the compressor is unloaded and reloaded as the air in the receiver rises or falls above and below the normal. For steam drive the speed is regulated and the air discharge controlled by a combined centrifugal and pressure governor.

'Brotherhood' High-Pressure Compressors for Air or Gas.

(*Peter Brotherhood, Ltd., Peterborough.*)

Brotherhood multi-stage compressors embody an exceptionally wide range of types resulting from development and research extending over sixty years. Standard types deal with pressures ranging from 600 to 6,000 lbs. per sq. in., in three to six stages of compression.

With the exception of compressors for oxygen, all piston and gland packings are of the metallic ring type, and except for special purposes, all classes have the working parts enclosed and lubricated under pressure.

Fig. 3 shows a three-stage air compressor for auxiliary air service for fuel injection and manœuvring in a motor ship.

The capacity of the compressor is 300 cu. ft. of free air per minute compressed to 1,000 lbs. per sq. in. at 350 r.p.m. The compressor is driven by a Brotherhood Force Lubricated Steam Engine developing 140 b.h.p.

Westinghouse Air Compressors.

(*Westinghouse Brake and Saxby Signal Co., Ltd.*, 82 *York Rd., King's Cross, London, N.* 1.)

The valve motion of the Westinghouse type of steam-driven air compressor is simple and compact, being entirely in the tophead, and all its parts are so arranged as to readily permit of examination or replacement. Should repairs to the valve mechanism be necessary, the tophead can be quickly removed and replaced by another, so that no unnecessary delay need occur through the compressor being put of service, pending repair. The air valves are contained in separate cases, so placed that they can readily be taken out.

The compressors are arranged vertically, and consist of a steam cylinder connected by a centre-piece to an air cylinder, or air cylinders, for either simple, compound, or three-stage compression. The three-stage compressor, figs. 4 and 5, is so constructed that air for compression is inhaled only on the upstroke of the piston, whilst on the downward stroke air at atmospheric pressure is drawn into and circulates around the inner walls of the cylinder and piston, to be again expelled on the succeeding upstroke; thus a supply of cool air is drawn into the interior of the compressor at every alternate stroke, and the compressor is air-cooled internally as well as externally; the result being that air compressed up to 300 lbs. per square inch is delivered at a temperature not exceeding 266° F., rendering the employment of water-cooled jackets unnecessary with this type of compressor.

For service on electric railways, the Westinghouse Brake & Saxby Signal Co., Ltd., manufacture air compressors driven direct by special slow-speed electric motors and also geared compressors driven by high-speed motors. Both of these types are equally suitable for industrial service.

Belliss High-speed Forced-lubricated Compressor.

(*Belliss & Morcom Ltd., Birmingham.*)

This type of compressor, fig. 6, p. 1195, embodies the best features of the Belliss engine, including the system of forced lubrication originated by the firm in 1890 (see Section XXX., Part III.). The working parts are generally the same as those for the 'O' type engine described in the section referred to. The air cylinders are water-jacketed and two-stage, as desirable for pressures in excess of 60 lbs. per sq. in., except in the case of quite small compressors.

WESTINGHOUSE THREE-STAGE AIR COMPRESSOR.

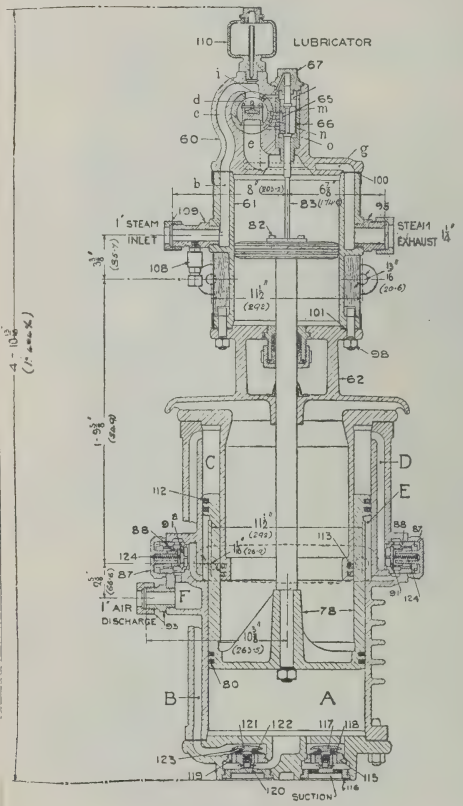

FIG. 4.

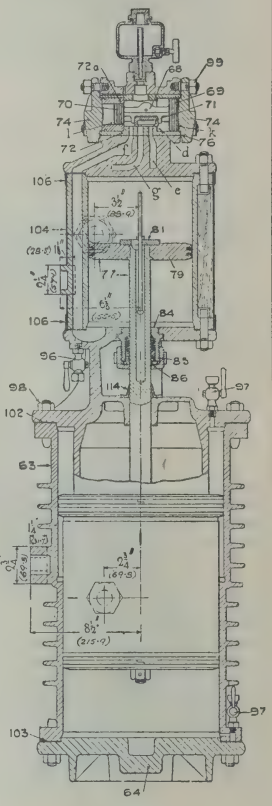

FIG. 5.

The compressor shown is adapted for being directly connected to an electric motor or for rope or belt driving. When operated at constant speed the air supply is controlled by an automatic valve on the inlet as shown, the valve being of the equilibrium double-beat type and con-

BELLISS AIR COMPRESSOR.

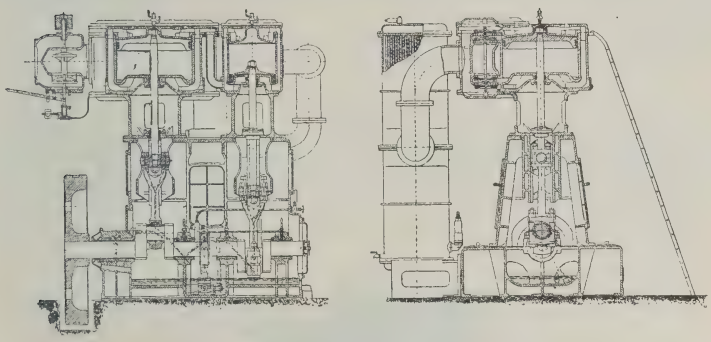

FIG. 6.—The Belliss Two-Stage Air Compressor.

trolled by an air relay, so designed that on the air pressure exceeding the intended pressure by 3 to 5 per cent. the air supply is cut off entirely, the pistons running *in vacuo* until the demand again causes the pressure to fall. As the air supply is not throttled the system is a highly efficient one. Special tests have demonstrated that the power required to run the compressor light

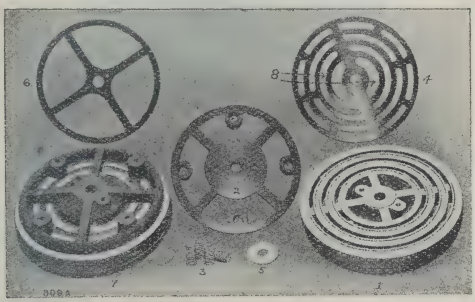

FIG. 7.—Details of Valves used in Belliss Compressors.

may be only 6 per cent. of the full power, and under 9 per cent. for the compressor and motor combined.

One of the chief points in the design of these compressors is the air valves. These are of the Rogier-Hoerbiger patent thin plate type, fig. 7, devised as the result of experience gained during the construction of the Simplon Tunnel, and which have come to be recognised as one of the best types of valves for air compressors. The valves consist of light discs of tempered

steel, perforated to give a multiple opening and falling on a cast-iron grid with suitable cushion and guard plates above. These valves are very reliable, noiseless in action, and a minimum amount of power is lost in operating them.

The Belliss compressors are also made with self-contained steam cylinders, controlled by the makers' patent relay type air governor, designed to vary the speed of the compressor in accordance with the demand for air, there being also a centrifugal governor directly connected to the crankshaft to prevent the speed under any conditions exceeding a predetermined maximum.

The Holman Single-Stage Compressor.

The Holman 'S' type compressor is a single-acting, duplex vertical machine. It is capable of working continuously at pressures up to 100 lbs. or intermittently to 110 lbs. per sq. in. It is made in four sizes, the largest having a displacement of 250 cub. ft. per min., and may be arranged for belt drive or for direct coupling to an electric motor or other prime mover.

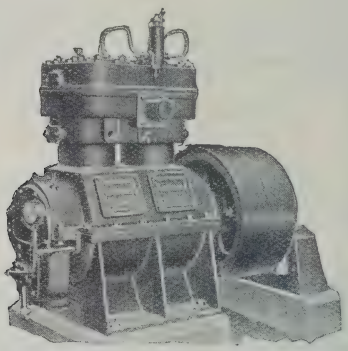

Fig. 8.—Holman 'S.' Type Air Compressor.

The cylinders and top portion of the casing are cast in one piece and the cylinder cover is removable. The suction and delivery flanges being on the cylinder, the cover may be removed without disturbing either suction or delivery air pipes.

The bearings are of die cast white metal and are adjustable, with the exception of the connecting rod small end which is solid bronze bushing. All bearings are supplied with oil under pressure from a valveless, gear-type pump driven from the crank shaft.

The valves are of the Rogler Hoerbiger type; all parts, with the exception of the seats, are interchangeable and the plates are of stainless steel. Each valve is situated in its own chamber, and water passages between suction and delivery chambers prevent the pre-heating of the incoming air.

Unloading is effected by the holding open of the inlet valve. The mechanism for this is controlled by a pilot valve which, connected to the air receiver, may be set to operate when the pressure in the latter reaches a predetermined maximum. The difference in pressure between unloading and resuming load may also be adjusted.

The three smaller sizes of this type are also incorporated in portable sets which may be either petrol engine or electric motor driven.

THE HOLMAN ROTARY PISTON AIR COMPRESSOR.

(Hele-Shaw Beacham Type.)

This type of compressor which was developed from the Hele-Shaw Rotary Oil Pump, has recently been simplified and is now becoming popular, especially where a light-weight, high-speed unit is required.

It is a single-stage machine with three cylinders, formed in one casting, which rotate on ball and roller bearings about a fixed water-cooled valve in which the air inlet and discharge passages are formed.

When the cylinder body is rotated a reciprocating motion is imparted to the pistons, each making an inward and outward stroke per revolution. The floating rings are mounted on ball bearings and are free to rotate. For this reason the gudgeon-pin bearings do not rotate, their motion being simply oscillatory, similar to the gudgeon-pin bearings of a single-acting engine.

During the outward stroke air is drawn into a cylinder through an opening at its inner end, a suitably positioned port in the central valve communicating with the inlet passage. At the commencement of the inward stroke the inlet port is covered, and the air is compressed until the delivery port is uncovered, when the air passes along the delivery passage through a non-return valve and thence to the air receiver.

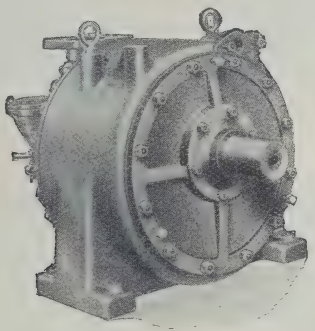

FIG. 9.—Holman 'H.S.B.' Type Compressor Unit.

Thus the same cycle of operations takes place as in a reciprocating type compressor with mechanically operated valves. One of the advantages of this design is that the machine may be run, with high overall efficiency, at higher speeds than is possible with an ordinary reciprocating machine, thus permitting direct coupling to an electric motor or other prime mover. Other advantages include: positive rotary valve action without operating mechanism, oil sealing for pistons and valve, reduced piston side thrust, dynamic running balance, uniform torque, compact form and light weight.

Two sizes of this type of compressor are made, the smaller for capacities up to 80, and the larger to 160 cub. ft. per min. displacement. Both are supplied as either stationary or portable sets; their light weight, small size and vibrationless running make them extremely suitable for the latter.

Besides the usual purposes for which portable compressors are employed, such as road construction, etc., these sets, because of their extreme portability, are very suitable for use in the more inaccessible districts which would be most difficult, if not impossible, to reach with compressors of the ordinary type.

The volumetric efficiency of the Holman Rotary Compressor is exceptionally high, and the isothermal efficiency is practically constant over the whole range of delivery pressures.

In the smaller sizes the compressor is readily portable, and is very compact.

THE HOLLAND 'SLM' ROTARY AIR COMPRESSOR.

(Bernard Holland & Co., 17 Victoria St., London, S.W. 1.)

(1) This Rotary Air Compressor, figs. 10, 11, consists essentially of a fixed casing or stator in which is a rotor fitted with blades free to move radially. As the rotor is less in diameter than the bore of the stator or casing and is placed eccentrically within it, there is a crescent-shaped space between

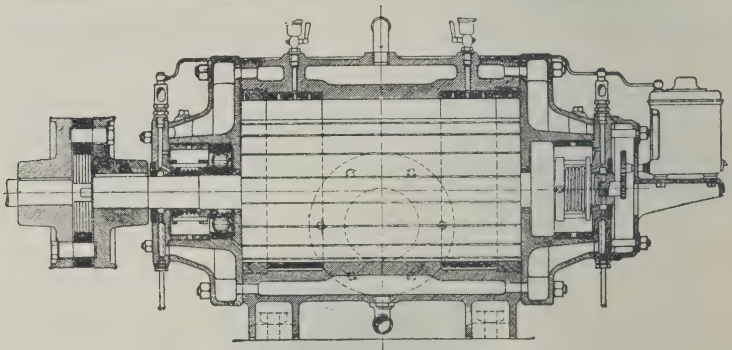

FIG. 10.—The Holland 'SLM' Rotary Air Compressor.

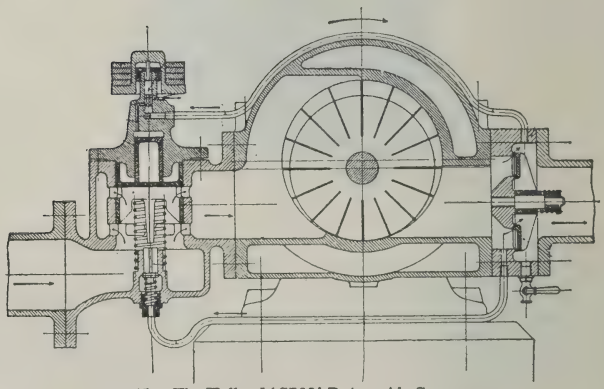

FIG. 11.—The Holland 'SLM' Rotary Air Compressor.

them. When the rotor is revolved, the blades, maintained by centrifugal force in contact with the casing, divide the crescent-shaped space into cells, which, each in turn, expand from a minimum to a maximum cubic capacity (suction period) and then decrease to a minimum cubic capacity (compression and delivery period).

Floating rings, one near each end of the rotor and revolving in unison with it, take the greater part of the thrust of the blades, so restricting and controlling their pressure on the wall of the casing; the consequent low friction and the absence of reciprocating parts and valves allow of this compressor being run at high speeds of revolution without vibration or perceptible wear after long use.

Metallic glands of special design dispense with the use of stuffing-boxes and packing. The lubrication is by pump, and is automatic.

Air-cooled single-stage compressors are made for pressures up to 10 lbs. per sq. in., and water-cooled single-stage machines for pressures up to 60 lbs. per sq. in. Water-cooled two-stage machines are supplied for pressures up to 150 lbs. per sq. in. and, dependent on size, up to 200 lbs. per sq. in. They are made in a number of standardsizes ranging from 6 cu. ft. to 4,000 cu. ft. delivery of free air per minute. For certain duties much larger units can be built.

The pumps are particularly suitable for continuous duty, coupled direct to electric motors and other fast-running prime movers; they are also arranged for belt and chain drive. They occupy little space, run without vibration, and need but inexpensive foundations.

(2) These machines can be so arranged as to perform the dual service of compressing and exhausting, one and the same machine being operated, at will, either as a compressor or as a vacuum pump. (See p. 1201.)

Air-Compressor Packing.

'BRITIMP' HOLLOW RING PACKING.

(*British Metallic Packings Co.* (1929), *Ltd.*, 7 *Princes Street, Westminster, S.W.* 1.)

This packing is largely used for high-pressure air and gas compressors, also for water-pumps, hydraulic accumulators, stop valves, emergency valves, expansion joints, gun recoil chambers,

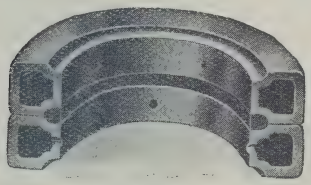

FIG. 12.

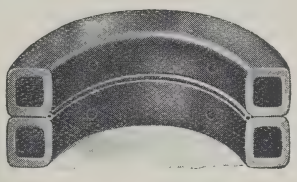

FIG. 13.

etc. The packing consists of hollow circular rings filled with graphite. The inner walls of the rings contain small holes through which the graphite is squeezed, thus providing the necessary lubrication. The rings are made in various forms to suit individual conditions. Two examples are shown in figs. 12 and 13.

See also pp. 1751, 1792, and 1903.

Air-Compressor Lubrication.

An oil suitable for air-compressors should always be highly filtered, because such oil will have a minimum tendency to form carbon deposits. Oils compounded with vegetable or animal oils are quite unsuitable for air cylinders.

Use only a straight-run, highly filtered, pure mineral oil of the lowest natural flash test consistent with the viscosity necessary to lubricate the cylinders and provide a proper piston seal.

The correct viscosities (worked out by the members of the Compressed Air Society, U.S.A., all of whom are builders of air-compressors) are given in the following tables, showing the proper specifications for both paraffin and asphaltic oils of various viscosities.

PHYSICAL TESTS OF PARAFFIN-BASE OILS. (*W. F. Osborne.*)

Cooling Water for Air Compressors.

Cooling water for cylinder jackets, cylinder heads, and intercoolers should always be turned on before the compressor is started. In case of stage compression, the greatest efficiency is obtained with the outlet water from the intercooler at a low temperature. The water supply to air cylinders and intercooler should be independent of each other, and the flow controlled by a valve on the inlet. The water should be shut off when the compressor is stopped, and in freezing weather all jacket drains should be opened. Outlet water should flow into open funnels so that frequent temperature readings can be made, a rise in temperature indicating deficient cooling, carbonised discharge valves, or leaking piston rings. The use of the thermo-siphon cooling system is not recommended.

NOTE ON AIR-COMPRESSOR OPERATION.

A bad practice in air-compressor operation is to put the air-discharge pipes through the intake duct. This serves directly to defeat the gain of the cool duct, because the hot discharge pipe heats the incoming air. On one such installation the incoming air was heated 6° F. by the presence of the discharge pipe in the intake duct. In this case there was a direct throwing away of about 1½ per cent. of power, which amounted to throwing away 11½ lbs. of coal every time 1,000 lbs. was shovelled into the furnace, day in and day out. In estimating such a heating loss a rough figure is 1 per cent. loss for each 5° F. intake-temperature rise.

VACUUM PUMPS.

THE BAILEY PATENT SLIDE VALVE 'DRY' VACUUM PUMP.

(Sir W. H. Bailey & Co., Ltd., Manchester.)

In the 'K' Vacuum Pump the slide-valve is without a stuffing-box, and the spring delivery valve is not carried by the slide-valve, but works vertically on a stationary seat, easily accessible even when the machine is running. By this arrangement the slide-valve does not run in the interior of the valve chest, but on the outside of it, and is, consequently, easy to fit and adjust; it has no stuffing-box to its spindle.

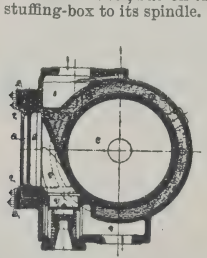

FIG. 14.

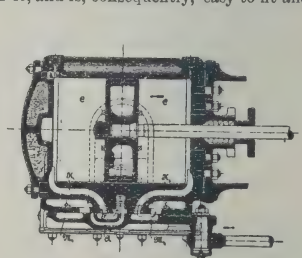

FIG. 15.

Fig. 14 shows a transverse section, and fig. 15 a longitudinal section of the standard air cylinder of the 'K' pump. The cylinder and back covers are water-jacketed, the front cover is cast in one with the cylinder, and a joint between the cylinder and the frame is avoided. In the larger sizes the front cover is water-jacketed.

The action of the valve is as follows :—

The air or gases enter by the suction pipe S and pass to the spaces S1 and S2. In fig. 14 the piston is passing towards the left-hand side and draws air into the cylinder from S2 through the space M2 and the port K2. At the same time it discharges the air drawn in during the preceding stroke by K1, P, and D, the slide-valve being set in relation to the crank so that the spaces S1 or S2 and D are put into communication at the right moment with the corresponding ends of the cylinder. Besides the ports M1 and M2, through which the gases pass into the cylinder, and the port P1 through which they are discharged, the slide-valve has a compensating or equalising port A which communicates between the discharge side of the piston and the suction side, thus equalising the pressure. When the piston has reached the dead point this port opens, for an instant of time, the communication between the two sides of the piston, the cylinder being cut off from the inlet and outlet by the slide-valve. The tension or pressure in the clearance space is thus reduced almost to the suction tension or pressure, and the piston can now draw air in much sooner, the effective suction stroke or volumetric efficiency being thereby increased. In addition to the slide-valve there is a spring valve V. The slide-valve governs the beginning and the end of both suction and discharge strokes. The spring valve has no effect on the volumetric efficiency of the pump, as without it the same volume would be drawn in, but it is necessary in order to reduce the power required to drive to the lowest possible limit. The slide-valve opens the suction and discharge at the beginning of each stroke and closes at the dead point so that the pump can be used for any degree of vacuum. The opening of the discharge port at a time when the air or gases are not yet compressed to atmospheric pressure would permit the air in the discharge pipe to flow back into the cylinder, causing back pressure and loss of power. The spring valve prevents this, as it separates the external air from the cylinder and prevents it from entering the cylinder when the slide-valve opens the discharge. When the air or gases in the cylinder are compressed to atmospheric pressure the spring valve opens automatically and the discharge commences. The influence of the spring valve therefore only affects the power for driving as previously stated ; it works vertically, is always accessible even when the machine is running, and is noiseless.

The single type pumps will maintain a vacuum of over 29·8 ins. of mercury when exhausting from a closed vessel. When a higher vacuum is necessary, the Bailey Double Vacuum Pump is recommended. This pump will maintain a vacuum of over 29·95 ins. of mercury at normal temperature and with a barometric pressure of 30 ins.

These pumps are particularly suitable as air pumps for condensers for steam engines, central condensation plants, cooling towers, condensers for evaporating plants, vacuum drying plants, distillers, filtering plants, etc.

The Holland 'SLM' Rotary Vacuum Pump.

(*Bernard Holland & Co.*, 17 *Victoria St.*, *London*, *S.W.* 1.)

This machine is rotary and is similar in general design to the Holland 'SLM' Compressor; it runs without vibration at the same high speeds of revolution and possesses all the characteristics of that machine, including the ability to perform, at will, the dual service of exhausting and compressing when arranged with the appropriate inlet and outlet piping. The single-stage air-cooled pumps will maintain a vacuum of 60 per cent. or 18 ins. of mercury with a barometric pressure of 30 ins., and under the same conditions the single-stage water-cooled pumps will produce a vacuum of 96 per cent. or 28·8 ins. of mercury, and the two-stage water-cooled machines, when exhausting from a closed circuit, will maintain a vacuum of over 99·9 per cent. or 29·97 ins. of mercury.

These machines, like the compressors, will run continuously with little attention, and maintain their efficiency after long use.

See also p. 1198.

Snifting Valves.

These valves open for the purpose of allowing the passage of air, but close if liquids attempt to pass ; they are used in hydraulic systems, and also in motor-cars. In a simple form the arrangement is shown by fig. 16.

B is a light float with a leather washer at the top ; O is an outlet pipe ; X is the pressure system. Air is free to pass in and out, but if liquid is passing out, B is carried up and seals the outlet pipe.

In connection with air vessels for pumps, a snifting valve is utilised to recharge such with air ; two cocks may be used, one at the top and one at the bottom of the vessel, so

that water may be drawn off below and air re-admitted above. If it be desired to admit it automatically while at work, a 'snifting valve,' a separate air-pump or an air-injector may be adopted. The valve, fig. 17, is placed between the suction and delivery valves, and

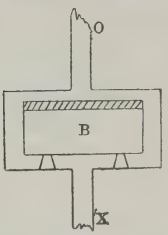

FIG. 16.

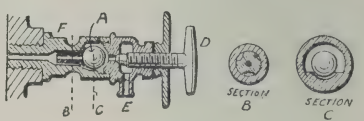

FIG. 17.

consists of a gun-metal chamber, F, containing a ball, A, which rolls backward and forward on account of the pump stroke. When rolled leftward, air is drawn inward at E, while the escape of water on return stroke is prevented by a rightward roll, and the whole may be put out of action or adjusted by a screwed plug, D.

PNEUMATIC DESPATCH TUBES.

Tubes.

The tubes used in the Pneumatic Despatch Service (telegrams only) of the British Post Office are 3, 2½, and 1½ inches in diameter, the 2½-inch being the size in most general use. The tubes are manufactured in lengths of about 28 feet. The tubes are of lead, and are enclosed in cast-iron pipes for mechanical protection. Each length of lead pipe is laid in a wooden trough as soon as manufactured, so that it may be handled without fear of bending. A tightly fitting polished steel 'mandril,' 1 foot long, and of the exact gauge of the tube, attached to a strong chain, and lubricated with soft soap, is then drawn through the entire length of the tube. This operation ensures the tube being smooth, cylindrical, and uniform throughout. The jointing of the lead tubes is effected as follows: Previous to the placing of the tubes in the trench, a strong chain is passed through it, and a polished steel mandril, 6 inches long and slightly less in diameter than the diameter of the tube, is heated and attached to the chain, and pushed half its length into the end of the tube already laid; the new length of tube is then forced over the projecting end of the mandril until the tube ends (which have been previously cut flat) butt perfectly together; a plumber's wipe joint is then made. By this means the tube is made perfectly air-tight, and the mandril keeps the surface of the tube under the joint as smooth as at any other part of its length. After the joint has been completed, the mandril is drawn out by the chain attached to it, the next length is drawn on and the process repeated.

Carriers.

The carriers in which the messages are placed consist of a cylindrical tube of gutta-percha covered with felt: a 'skirt' projects beyond the open end of the carrier. The pressure behind causes the skirt to expand until it exactly fits the tube and thus prevents the air leaking past. The front of the carrier is provided with a buffer or piston, formed of several discs of felt, which exactly fits the tube. To prevent the messages getting out of the carrier, the end is closed by an elastic band, which can be stretched sufficiently to allow the messages to be put in.

The length, over all, of a carrier for a 2½-inch tube is 6⅔ inches; the inside measurements of the gutta-percha tube or message holder being—length 4⅔ inches, diameter 1½ inches. The weight of such a carrier when empty is a little over 3 ounces.

The 3- and 2½-inch carriers will, on the average, take 65 and 25 messages respectively.

The speed of the carrier may be roughly stated to range from 20 to 30 miles an hour for tubes not exceeding a mile in length.

Working Pressure and Vacuum.

The standard pressure is 10 lbs. per sq. in., and the standard vacuum 6½ lbs. per sq. in.

For a given effective pressure, carriers travel most rapidly in pressure tubes when the air supply is *intermittent*, *i.e.* when the message tube is only connected with the compressed air mains during such times as carriers are actually traversing the tubes. The reason of this is, that

the compressed air with which the portion of the tube in front of the carrier is full, and which has to be displaced by the advancing carrier, weighs more than the uncompressed air, and consequently requires a greater amount of power to move it. The difference in the two cases is, however, not great, but the higher the pressure the greater is the difference in speed due to this cause. With 6 lbs. pressure, the carrier takes only 3 per cent. longer time with continuous than with intermittent working, whilst with 14 lbs. pressure it takes nearly 6 per cent. longer time.

In the case of carriers propelled by the exhaustion of the air, if the exhaustion is not commenced until the carrier is inserted at the further end, then the carrier commences to move as soon as the exhaustion at that end reaches a few ounces only, and the full exhaustion effect is not felt until the carrier has been moving for some time. When, however, the exhaustion is continuous the carrier on its insertion practically starts off under the full pressure: hence its speed is greater than in the first case. The continuous system of vacuum working, where one tube is used for the 'up' traffic (*i.e.* the traffic from the distant to the central or 'power' station) only, is easily effected, whether the traffic is heavy or light; but the intermittent system for the 'down,' or pressure working, which, as pointed out, gives the greatest speed, cannot always be followed out, as during the busy hours of the day the carriers have to be despatched in such quick succession that the current of air in the tube is practically continuous.

Power Required to Work Tubes.

The actual power required for working *continuously* the tubes at a pressure of 10 lbs. per square inch (the standard pressure) is, theoretically, 3·35 horse-power for a 2¼-inch tube 1 mile long; but in practice 50 per cent. requires to be added to allow for losses from various causes, *i.e.* the actual horse-power should be 5. With 10 lbs. pressure the time occupied in the transit of a carrier through a tube 1 mile long is 2½ minutes.

In order to neutralise the intermittent action of the pumps, and ensure a uniform flow of air, reservoirs or 'containers' are provided. These are arranged to have sufficient capacity to give out a reserve supply when the load on the tubes becomes abnormal, as occasionally happens.

For a given transit time the actual horse-power required is much less in the case of vacuum than in the case of pressure working. Thus, for example, the transit time for 10 lbs. pressure is the same as for 6½ lbs. vacuum, but the horse-power required in the two cases would be as 1·83 to 1. Inasmuch, however, as the tubes cannot practically be worked only by vacuum, the calculations for transit time and horse-power must be based on pressure working. The actual power necessary must be largely governed by local conditions, and no definite rule can be laid down. The power required to work any tube or number of tubes is usually computed, however, on the estimated traffic in carriers per hour which each tube is required to carry. This figure multiplied into the volume of the tube and divided by 60 gives the volume of air swept out per minute (if there is a number of tubes the figures are of course aggregated), and this affords the capacity of the pump at the required pressure.

Pumping Machinery.

The air compressors used for this system are driven by electric motors, oil, steam, or gas engines, and are provided according to the present standard practice with one or more cylinders arranged to draw from the vacuum container and compress the air thus drawn into the pressure container. Automatically controlled auxiliary valves are interposed in the inlet and delivery mains of the pump. They are controlled pneumatically by means of a by-pass connection with the pressure container in such manner that if (*a*) the pressure in the pressure container is low and the vacuum in the vacuum container high, so that the pump is deprived of air to compress, the auxiliary inlet valve on the vacuum main opens to atmosphere and admits free air for compression until the pressure in the pressure container is restored, when the valve shuts. On the other hand, (*b*) if the vacuum is low and the pressure is high, so that the pump would have to discharge against considerable back pressure the air it exhausts from the vacuum container, the auxiliary valve in the pressure main opens to atmosphere until the vacuum is restored. A non-return valve on the container side of each auxiliary valve prevents the loss of pressure or vacuum whilst either auxiliary is open to atmosphere. This system, besides economising in plant and space, absorbs and utilises certain losses which are inevitable with independent pumping for both services.

Transit Time.

Table I. enables the transit time for any diameter and length of tube at any pressure to be calculated, and from Table II. can be ascertained the pressure required to drive a carrier through any tube in any time. The chart, fig. 18 (p. 1206), based on Table I., shows the Transit Time variation for different lengths of tubes of three sizes, 1¼ in., 2¼ ins., and 3 ins., each worked at 10 lbs. pressure.

I.—Tables for calculating Time of Transit of a Carrier through a Tube.

Formula: $t = \cdot00872\sqrt{l^3} \times \frac{1}{\sqrt{P}} \times \frac{1}{\sqrt{d}} = A \times B \times C$ secs.

$A = \cdot00872\sqrt{l^3}$.

Example : Required, the pressure, P, to drive a carrier through a tube 5 ins. in diameter (C_1) and 2.000 yds. long (A_1) in 200 secs. (B_1). P = 608,000 × ·0000250 × ·200 = 3 lbs.

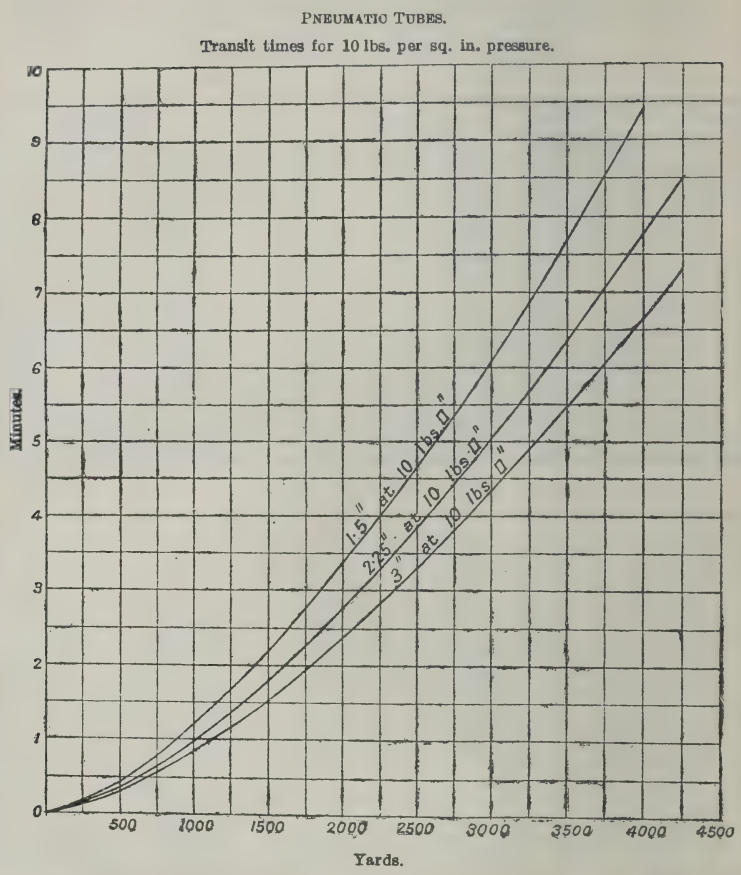

FIG. 18.

PNEUMATIC HOUSE TUBES.

These are, in the British Post Office Service, usually of brass or copper, and in some cases are operated on lines similar to the foregoing system, but considerable modifications have been introduced.

A very general system for warehouses is a circular one with loops into the various apartments which it is desired to connect.

The air is continually circulated by means of a blower of the Roots type which is joined at one end of the tube, whilst the other is open to atmosphere.

Carriers are despatched from a station by being inserted in the 'return' pipe of the loop and are received on the 'flow' pipe, suitable receiving apparatus being provided for the interception of a withdrawal of the carrier without interrupting the flow of air, which is made to travel through a bye-pass.

SECTION XXIV

REFRIGERATION—REFRIGERATING MACHINERY—ICE MAKING—COLD STORAGE.*

(Contributed by Hal Williams, M.I.Mech.E., M.I.E.E., Consulting Engineer, and A. G. Clausen, A.M.I.Mech.E.)

Refrigeration, or the mechanical production of low temperatures for commercial use, is a process of removing heat at a low level and discharging it at a high level on the thermometer scale.

In a steam-power plant heat is applied to evaporate water in a boiler; a small proportion of the heat supplied is converted into useful work in the engine, and the balance which cannot be utilised is rejected to the condensing water.

A refrigerating machine is simply a reversed heat engine; the cold air machines are now obsolete, and in all modern plant heat is taken up by the evaporation of some suitable working fluid termed the 'refrigerant,' and more heat is applied, generally in the form of power, to compress the resulting vapour to such a pressure that it can be condensed.

The sum of the heat taken up by evaporation and that added as power is then discharged in a condenser, to water of the prevailing normal temperature, the refrigerant is condensed, and as a liquid is in a state to complete the cycle of operations.

The performance of a refrigerating machine is the ratio of the number of heat units abstracted to those applied as power, and for a reversible cycle with a perfect fluid is $\frac{T_1}{T - T_1}$

where

T = absolute temperature of condensation;
T_1 = „ „ „ evaporation.

A refrigerating machine working on the compression system—which is practically universal—is shown diagrammatically in fig. 1 (see p. 1210) and consists of four essential parts:

(1) The evaporator or refrigerator, in which the refrigerant boils or evaporates at a low pressure and temperature.
(2) A gas pump or compressor to withdraw the vapour formed in the evaporator and compress it to such a pressure that it can be condensed by the water supply available.
(3) The condenser in which the compressed gas is condensed at a high pressure.
(4) The regulating or expansion valve, provided with fine adjustment to control the rate of flow of the condensed liquid from the condenser into the evaporator.

Starting with the liquid refrigerant in the condenser, the thermal cycle is as follows:

The liquid at condenser pressure and temperature is permitted to flow through the regulating valve into the evaporator.

On passing the valve a proportion immediately evaporates, taking up its latent heat from the remainder, which in this way is cooled to the evaporator temperature.

The remainder evaporates at constant pressure and temperature, taking up its latent heat from the air, brine, water, or other substance that is in contact with the exterior surface of the evaporator, and which is correspondingly reduced in temperature.

The proportion of the liquid evaporated to cool the remainder to the temperature of evaporation is not available for refrigeration, and represents a loss as compared to the ideal or reversible cycle.

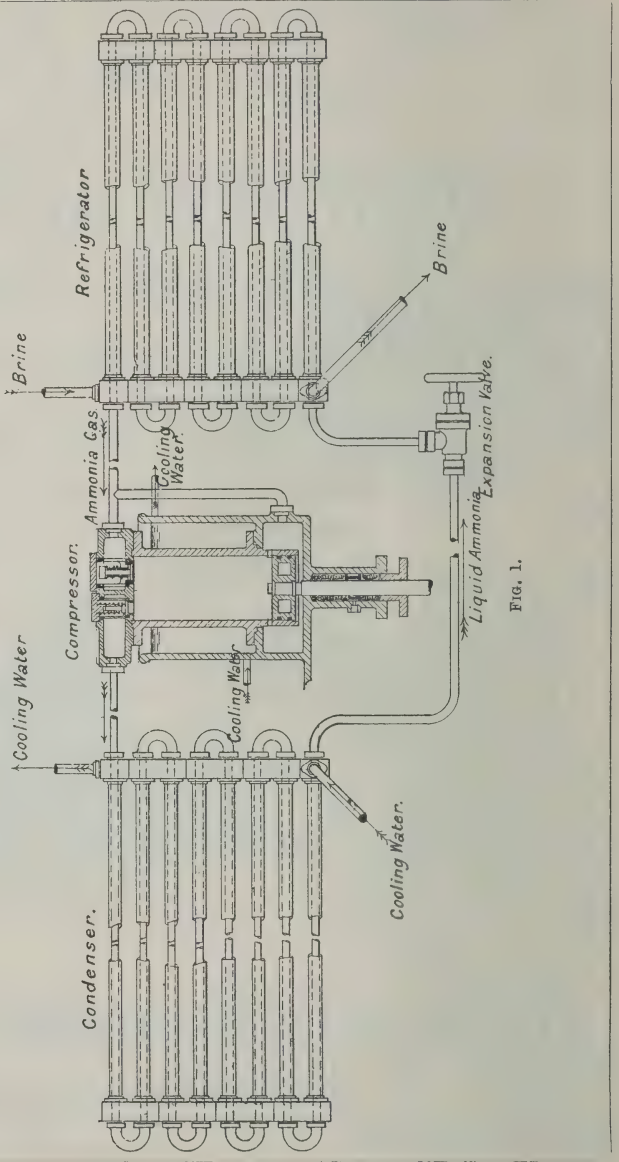
The liquid should therefore be cooled to as low a temperature as is practicable by ordinary means before passing the regulating valve, and its specific heat, considered as a fraction of its latent heat, should be low.

The vapour leaving the evaporator may be either:

(*a*) In a dry saturated state;
(*b*) Slightly superheated, or having its temperature a few degrees above its saturation temperature.
(*c*) In a wet state, or carrying with it some particles of unevaporated liquid.

With (*a*) and (*b*) the condition of working known as 'dry compression' is obtained and the work of compression, converted into heat, raises the temperature of the refrigerant so that it is discharged from the compressor in a superheated condition.

* For further information the reader is referred to 'Mechanical Refrigeration,' by Hal Williams (Sir Isaac Pitman & Sons, Ltd.), from which publication certain of the tables and data included in this section have been condensed.



THE COMPRESSION SYSTEM.

FIG. 1.

A small proportion of the heat of compression can be absorbed by water jackets on the discharge side of the compressor. Owing to the low initial temperatures, complete water jacketing cannot be used as with air compressors, as it would cause losses through initial superheating.

With (*c*) the heat of compression is either partially or wholly taken up by the evaporation of the entrained liquid, and the state of working known as ' wet compression ' is obtained when the incoming vapour carries just sufficient liquid to maintain the refrigerant during compression at the temperature corresponding to its saturation pressure.

In practice the refrigerant is as a general rule at some point between the states giving either completely dry or wet compression.

In the condenser the gas, if superheated, must first be cooled down to its saturation temperature. when the process of condensation proceeds.

In order to permit the transfer of heat, the temperature of evaporation must be below that to which the air or brine is to be cooled, and similarly the temperature of condensation must be above that of the cooling water used.

The greatest efficiency is obtained when the temperature of evaporation is as high and the temperature of condensation is as low, as possible, so that the surfaces for heat transfer should be large to keep the necessary differences small.

The refrigeration effected per pound of refrigerant can be obtained directly from the tables of properties of the various fluids, by deducting the total heat of the liquid at the condenser temperature from the total heat of the saturated vapour at the evaporator temperature.

The volume of gas that must be pumped by the compressor can be obtained directly in the same way.

The amount by which the actual swept volume of the compressor must be greater than the net volume of the gas, will depend upon the characteristics of any particular compressor and the conditions of working, and averages about 25 per cent.

The power required to drive the compressor can be obtained directly from the Mollier or from the entropy diagrams, or from indicator diagrams for the compressor.

The heat that must be transferred to the condensing water is the sum of the heat abstracted or effective refrigeration, and the heat equivalent of the work done in compression.

The quantity of water required will vary directly with the permitted rise in temperature.

The selection of a working fluid is governed by its limits of pressure and volume over the normal range of temperatures, its critical pressure, and the relative values of its specific heat as a liquid and its latent heat.

Other factors are its action, if any, on the materials used for the construction of machinery or on lubricating oils, its poisonous properties, and its inflammability.

There are many fluids that can be used, but by far the most important are Ammonia and CO_2. Sulphuric ether was often used in the early days of refrigeration, and SO_2 has been employed to a considerable extent on the Continent of Europe.

SO_2 methyl-chloride, occasionally ethyl-chloride, and other fluids, are also used for the very small machines of the household type that are now made in large numbers.

Ammonia Compression Refrigerating Machines.

Ammonia is generally considered to be the most satisfactory and economical refrigerant. It has a high latent heat, and over the normal temperature range the pressures and sizes of parts are comparable to ordinary steam and air compressor practice.

The gas has a highly pungent odour and is irrespirable, so that great care must be exercised in working or in overhauls, to prevent dangerous leakages.

It is exceedingly soluble in water, and one volume of water at 60° F. will absorb 600 volumes of gas.

Ammonia attacks copper and its alloys, so that none of these must be used for parts of the machine with which it comes in contact.

The figures given in Tables II. and III. are for compressors working with dry or practically dry compression. They represent the average results that are obtained with machines of moderate size, but the variations in performance and power naturally vary to some extent with the characteristics of different makes.

With wet compression, both the number of B.Th.U.'s abstracted and compressor I.H.P. are reduced per unit compressor volume, and theoretically the performance, or ratio of $\frac{\text{B.Th.U.'s}}{\text{I.H.P.}}$, is slightly superior, though in practice dry compression gives the best results.

Carbonic Acid Refrigerating Machines.

CO_2 occupies a unique position in the group of fluids used for refrigeration in that its critical temperature (88·4° F.) often comes within the working range; also its specific heat is high, and its latent heat relatively low.

Its efficiency with condensing water at about 50° F. is but little inferior to that of the ammonia machine, but falls away more rapidly with an increasing condenser temperature. There is, however, no break in the curves of capacity at the critical temperature.

CO_2 is inodorous, and it is stated that air containing up to 8 per cent. can be inhaled without danger, though at higher percentages it causes stupefaction and suffocation.

The quantities used in machines are, however, such that even if the whole charge were to escape, in any ordinary situation, it is hardly likely to produce a dangerous concentration, and on this account the Board of Trade regulations permit CO_2 machinery to be installed in the engine-room or similar space on board ship, whereas ammonia machines must be housed in a special deck-house.

CO_2 does not attack any metals, so that condensers can be constructed of copper piping, and these advantages have given it a predominant position for marine refrigeration.

Although the pressures are high, the diameters of all parts are small, so that there are no constructional difficulties.

14	25·19	1·43	1·69	1·99
23	29·03	1·34	1·62	1·97
32	33·29	1·22	1·50	1·90

The figures given in Tables V. and VI. are for ordinary CO_2 compressors working with dry compression. They represent the average results that are obtained with compressors of moderate size, but the variations in performance and power naturally vary to some extent with the characteristics of different makes.

To obtain the best results in working, a CO_2 machine should be run with the suction gas in a dry saturated state, or even slightly superheated. When leather piston and gland packings were used this was impracticable, as the leathers were burnt by the temperatures reached with dry compression. All modern CO_2 machines have piston rings and metallic gland packings, so that there is now no difficulty in running a CO_2 machine to give the best results that can be obtained.

With high condensing temperatures the performance of a CO_2 machine can be appreciably improved by permitting the cooling of the liquid by its own partial evaporation to take place in two stages.

The compression also takes place in two stages: in the first the vapour from the liquid that has effected refrigeration, plus that from the second stage of the partial evaporation for liquid cooling, is compressed to the pressure at which the first stage of partial evaporation ends, when the whole of the vapour is compressed to the condensing pressure.

Other Refrigerants.

Both the theoretical and practical performance of other fluids used approximate closely to the results obtained with Ammonia, but the B.Th.U.'s extracted and compressor I.H.P. as shown in the tables should be divided by the following factors :

For Sulphur Dioxide	2·89
For Methyl Chloride	1·94
For Ethyl Chloride	6·57

The principal characteristics of these refrigerants, taken at 32° F. are :

TABLE VII.—REFRIGERANTS.

Refrigerant.	Absolute Pressure. Lbs. per sq. in.	Volume Vapour. Cu. ft. per lb.	Specific Heat of Liquid.	Latent Heat. B.Th.U.'s per lb.
Sulphur Dioxide .	22·45	3·41	0·322	156·8
Methyl Chloride .	36·63	2·68	0·467	174·6
Ethyl Chloride .	8·90	8·88	0·376	168·9

With very small machines, which receive practically no skilled attention, low working pressures are an advantage in reducing the risks of leakage, but pressures below the atmosphere should be avoided, as inward leaks of air cause difficulties in working, and any moisture carried in may combine with SO_2, forming sulphuric acid, which corrodes the parts.

Compressors.

Both single-acting and double-acting compressors are made in a large variety of designs and sizes, and during the last few years there have been great developments in high-speed forced lubrication machines suitable for direct coupling to electric motors.

With the exception of machines made by Messrs H. J. West & Co., Ltd., who employ a sleeve valve, all valves are of the automatic type, the high-speed compressors using light ring and plate valves of similar character to those developed for air compressors.

Most single-acting ammonia compressors are made of the enclosed type and work with ammonia at the suction pressure in the crankcase. The gland is of the rotary type on the crankshaft, and it is sealed with oil from the pressure lubricating pump. These machines have trunk pistons, the lower portion of which forms the crosshead, and is fitted with oil scraper rings. The upper forms the piston proper, and the suction ports in the cylinder walls lie between the limits of the travel of the upper and lower parts.

The suction valves are placed at the top of the piston, and the delivery valves in a spring-loaded false or safety head.

The arrangement enables the maximum valve port area to be provided with a minimum clearance space; the gas passes through the compressor in one direction, so that the upper portion can be effectively water-jacketed, and it is claimed that the 'Uniflow' principle increases the compressor efficiency.

The safety head is a valuable feature, as it will lift and save any risk of accident in the event of liquid ammonia or oil passing into the compressor.

These machines are always of the vertical type, and are made with from one to four cylinders.

Double-acting compressors are made both in the horizontal and vertical types, and the valves are arranged either in hemispherical end covers or round the circumference at each end of the cylinder.

Double-acting compressors usually have the gland constructed in two portions, with a central space or lantern between them. The lantern space is connected to the suction side of the compressor, so that the outer portion of the gland is subjected to the low and steady suction pressure only, and any gas leaking past the inner portion is retained in the system.

CO_2 compressors are now almost invariably machined from high carbon steel forgings to ensure strength and the necessary gas-tightness, and for the same reasons all stop valves and fittings are of mild steel and machined from the solid.

Double-acting compressors are general except in the smallest sizes; the gland is provided with a lantern which is sealed with oil at a rather higher pressure than the compressor is delivering against.

This higher pressure is obtained by using a differential piston in a cylinder, connecting the greater area to the gas delivery and the lesser area to the oil space in the gland, a small hydraulic pump being used to make up any oil leakage.

In refrigerating machinery, absolute gas tightness is essential, and it is usual to test compressors and all other parts subject to gas pressure by hydraulic test to about three times the normal maximum pressure; also to test them when immersed in water with compressed air to about one and a half times the normal maximum pressure to show up any minute leaks or porosity in materials.

Condensers.

Condensers are made in three general types:

Submerged Condensers consist of a coil, or series of coils, of piping connected to headers, contained in a tank or casing, generally of circular form, through which the water is passed.

Atmospheric Condensers consist of coils in vertical stacks, over which the water flows, erected in the open air and standing over a collecting tank. These are often made of large size, and the water continuously recirculated so that they function also as recooling towers and only require a small make up supply.

Double Pipe Condensers consist of a number of concentric pipes, arranged in series as shown in Fig. 1 (p. 1210); the water passes through the inner pipe and the gas condenses in the annulus between the two pipes. The gas and water traverse the pipes in opposite directions, so that the condenser is counter-current, and on account of the high water velocities the rate of heat transfer is high.

Evaporators.

A refrigerating machine may be used either to cool brine or water that is in turn circulated through the cooling appliances used, or it may be arranged so that the evaporator piping itself forms the cooling appliances, and this method is referred to as direct expansion.

Brine Cooling Evaporators may be either of submerged coil or double pipe construction, or for ammonia or other low pressure refrigerants they may be of shell and tube form, the ammonia evaporating in the shell around the tubes through which the brine is circulated in either one or more passes, depending upon the quantity and velocity required.

Evaporators for Cooling Water are frequently made of the open type where the water trickles over the outside of the coils to avoid the danger of freezing up in any confined spaces.

The Direct Expansion System may be applied for several purposes, but is generally only used for cooling cold storage rooms.

The piping may be fixed directly in the rooms, or nested together to form an air-cooling battery, with a fan to circulate air over it and through the rooms by a system of ducts.

This type of air cooler must have a circulation of brine maintained over the piping to keep the surfaces free from frost where temperatures below freezing-point are required, or otherwise the accumulation of snow and frost would rapidly choke it up.

Heat Transference.

The proportions of the condenser and evaporator are determined by the rates of heat transfer that can be obtained.

The rate of heat transfer is directly proportional to the temperature difference. It varies as a power of the velocity V, and may be generally taken as $V^{0.75}$.

The rate of heat transfer varies with the temperature, viscosity, density, and state of the fluids in contact with the surfaces, and to secure satisfactory operation over a long life it is necessary to allow for deposits on and deterioration of pipe surfaces.

The rate of heat transfer through iron pipe and under the conditions usually prevailing in refrigerating machinery may be taken as being approximately as follows:

	B.Th.U.'s per sq. ft. surface per hour and per 1° F. mean temp. difference.
In submerged condensers	40 to 45
Atmospheric condensers	60 to 70
Double pipe condensers with a water velocity of 3 feet per second	100 to 120
Submerged brine coolers	35 to 40
Double pipe or shell and tube brine coolers with a brine velocity of 3 feet per second	80 to 90
Direct expansion or brine piping in a room with natural air circulation only	2·0 to 2·5
Air coolers with fans and forced air circulation and an air velocity of 10 feet per second	6 to 7

To conform with general practice, pipe surfaces should be so proportioned that the mean temperature difference between the refrigerant and the brine or water is 10° to 15° F., and in the piping for rooms a difference of 15° to 20° between the air and the refrigerant or brine.

Indicator Diagrams.

The indicator diagram gives an exact measure of the indicated horse-power developed in a compressor, and if it is compared with an indicator diagram taken when the machine is new and in good condition, it will disclose any defects in working such as leaky valves or piston rings.

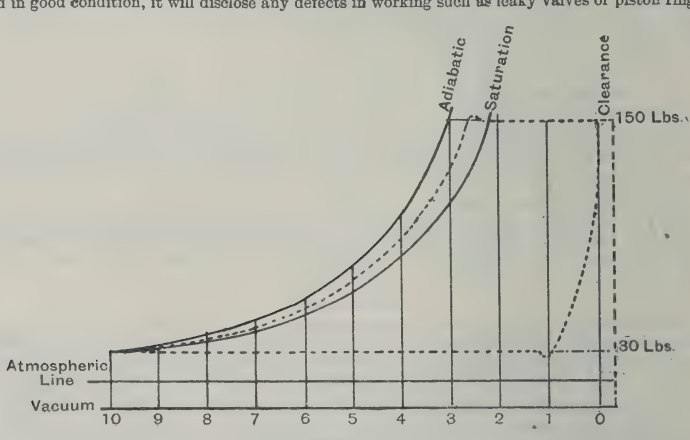

FIG. 2.

In order completely to analyse the indicator diagram, it is necessary to draw on it the curves for adiabatic compression, and for compression at saturation temperatures, as is shown in fig. 2.

With ammonia, the exponent for adiabatic compression is 1·29 and the compression curve follows the formula $P \cdot V^{1\cdot29} = C$.

The saturation curve can easily be plotted from the volumes given in the table of properties.

The actual compression curve will lie between these two, and in the case of dry compression it will be close to the adiabatic line.

The horizontal suction and delivery lines should practically coincide with the gauge pressures. If the gauges read correctly, and the difference is more than one or two pounds, it shows that there is a restriction through the valves which may be due to either too heavy springs, the valves not working freely, or insufficient areas in the ports.

At the points where the valves open, there is always a peak on the pressure line due to the difference in pressure required to lift them from their seats, but these peaks should only be small.

The re-expansion of the gas remaining in the clearance space at the end of the stroke follows approximately the same curve as that formed on the compression stroke.

The effective swept volume of a compressor, which is indicated by the length of the suction line, is thus reduced with the proportion of the clearance volume, but as the power required is correspondingly reduced, a moderate amount of clearance does not seriously affect the performance, though it may make a considerable difference in the output of compressors with otherwise similar dimensions.

If the compression curve approaches or overlaps the adiabatic line, it indicates a leakage from the condenser side, back into the compressor through the delivery valves or the joint rings of their seats.

If the compression curve approaches the saturation line, it indicates a leakage either through the suction valves or past the piston rings.

If the diagrams from each end of a double-acting compressor are compared, and a falling away of the compression line occurs at one end only, it indicates that the leakage is at the suction valve there. If both ends are similar, it may be either the valves, the piston rings, or both that require attention.

Ammonia Absorption Machines.

Ammonia absorption machines are only used in special cases where there is sufficient live or preferably waste steam which can be utilised.

The arrangement is shown diagrammatically in fig. 3, p. 1218.

In place of the compressor the ammonia is absorbed by cool weak liquor, which, being thus enriched, is pumped into a generator or boiler, where it is heated, and the ammonia driven off into the condenser.

An interchanger is provided to heat up the cool rich liquor passing to the generator, and at the same time cool down the hot weak liquor returning to the absorber.

The small 'Electrolux' refrigerator working on the absorption system makes most ingenious use of Dalton's law of partial pressures by introducing an inert gas into what is normally the low pressure side of the system. The total pressure throughout is maintained constant, so that circulation of the liquid can be effected on the thermo-syphon principle without any moving parts. At the same time the partial pressure of the ammonia in the evaporator is low enough to effect refrigeration.

Small and Automatic Refrigerating Machines.

The use of very small refrigerating machines, both for commercial and for domestic purposes, is now extending very rapidly, and their employment has been considerably stimulated by the recent 'Pure Food Act.'

With the exception of the Electrolux machine referred to, practically all these machines work on the compression system. They are so equipped that they are completely automatic in their operation, and standard models are driven by electric motors ranging from $\frac{1}{4}$th b.h.p. to 2 b.h.p.

A low-pressure refrigerant, generally SO_2 or methyl chloride, is used to simplify the construction and to minimise the risk of leakage at the gland, compressors are of the enclosed type, and the crankshaft gland is usually provided with a collar on the shaft, maintained by means of a spring in contact with a floating ring attached to the crank case by a syphon.

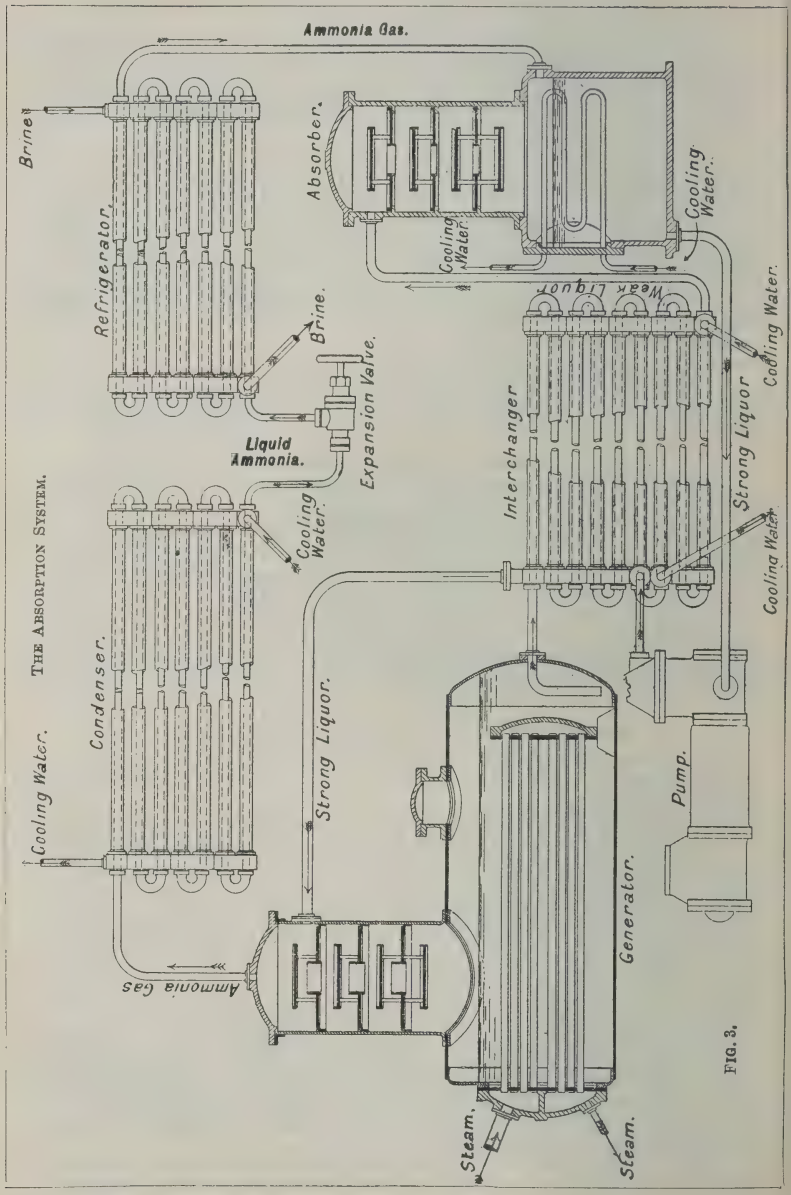
The compressors are started and stopped at predetermined temperatures by means of a thermostat operated mercoid switch, and a similar switch is fitted as a safety device to stop the motor if the condensing pressure rises to some point in excess of the normal working pressure.

In the smallest machines the condensers are air cooled, a fan either separate or framed in the compression fly-wheel being used to circulate air over it. In larger sizes the condenser is water cooled, and the flow of water is governed by a diaphragm controlled valve operated by the condenser pressure so that water only flows when the machine is in operation.

Automatic regulating valves are either of the float type operating by the level of the liquid refrigerant, or of the diaphragm type with a needle valve operated by the difference in pressure.

By far the largest numbers of small machines use SO_2 as a refrigerant, and a float type of regulating valve works in a receiver on the evaporator side, this receiver is also provided with an overflow pipe to return direct into the crank case any lubricating oil that has passed over.

There is a strong tendency for automatic features to be applied to rather larger units than the small self-contained plants, and many of these are working satisfactorily, but difficulties arise where more than one separate duty has to be performed.



THE ABSORPTION SYSTEM.

FIG. 3.

Ice Making.

The manufacture of ice is one of the principal uses of refrigeration, and the method now almost universally employed is the 'can' system, where the ice is made by placing cans or moulds containing water in a tank containing brine cooled to a temperature of 10° F. to 15° F.

When distilled and de-aerated water is used, the ice made is clear and transparent, but if ordinary water is frozen without agitation, the ice is soft and opaque, due to the minute bubbles of air dissolved in the water.

By agitating the water during the time of freezing, these air bubbles are swept off the ice surface, and the block made is clear, with the exception of a central core formed of the dissolved salts, the extent of the core depending on the hardness of the water.

Agitation can be effected by stirrers, but the best system in all except the smallest plants is that of blowing air through the water.

The time required for freezing can ice with brine at 15° F. is approximately :

Thickness of ice in inches	3	4	6	8	10	12
Time of freezing in hours	6	10	18	30	46	64

Ice moulds are made in a great variety of sizes to produce blocks of definite weights up to 4 cwts. each, which is a usual size for plants of large capacity, these blocks measuring about 22 in. wide, 11 in. thick, and 60 in. long.

The moulds must be made with a slight taper to enable the ice to slide out freely, and usually a number are secured together in a row, and handled as one unit by a crane.

The ice tank is arranged to contain the evaporator, which may either be of coil piping, or of the shell and tube type, and a vigorous circulation of the brine in the tank is maintained by means of a propeller or centrifugal pump.

A row of ice moulds when lifted from a tank is dipped into a thawing tank containing warm water to release the blocks of ice from the cans. These are then lifted, placed in a swinging tipping frame, and turned over so that the blocks slide out.

The empty row of moulds is then refilled with the correct quantity of water on one operation by a filling tank. One cubic foot of ice at 32° F. weighs 57·5 lbs., or 30 cubic inches weigh one pound.

In a temperate climate, and with a medium or large plant, about 230 B.Th.U.'s are required to produce one pound of ice from water at 65° F., and about 60 kw. hours are required with a motor-driven plant per ton of ice made. In warmer and tropical climates these figures are considerably increased.

Refrigerating Power.

The output of a refrigerating machine is often stated in Tons Refrigeration, and the standard American rating is then generally referred to.

One ton refrigeration is then equal to 288,000 B.Th.U.'s per day, or 12,000 B.Th.U.'s per hour when working with an evaporator temperature of 5° F. (— 15° C.) and a condensing temperature of 86° F. (30° C.).

Cold Storage.

The average temperatures maintained in cold storage rooms are as follows :

Butter—frozen .	10° F. to 12° F.	Hops	28° F.
Butter—short storage	32° F. „ 35° F.	Meat—frozen . .	15° F. to 16° F.
Cheese . . .	35° F. „ 40° F.	chilled . .	29° F. „ 30° F.
Eggs . . .	29° F. „ 31° F.	fresh . .	36° F. „ 38° F.
Furs and Fabrics .	30° F.	Fish—frozen . .	10° F. „ 12° F.
Fruit—Apples . .	32° F. „ 35° F.	fresh . .	30° F. „ 32° F.
Pears . .	35° F. „ 36° F.	Dried Fish—frozen .	15° F. „ 16° F.
Peaches .	32° F. „ 38° F.	for short storage	32° F. „ 35° F.
Oranges .	45° F. „ 50° F.		

Cold storage temperatures should, as far as possible, be maintained constant without variation. Both this and the maintenance of a definite temperature are particularly important where the temperature required is in the neighbourhood of the freezing-point. For produce that is frozen hard, an exact storage temperature is not quite so important, but variations should also be as far as possible eliminated.

The refrigerating power required for cold storage rooms varies very greatly with their size, shape, insulation, quantities of warm goods brought in and methods of working, but for ordinary storage rooms is about :

Capacity of Cold Rooms in Cu. Ft.	Temperature. 30° to 35° F. Tons Refrigeration.	10° to 15° F. Tons Refrigeration.
1,000	0·5	0·8
10,000	2·5	4·0
100,000	12·0	20·0

These figures assume continuous operation, and for reduced hours must be proportionately increased. The surface and extent of the cooling appliances will vary with the refrigerating power required and conditions of working.

The quantity of piping fixed in a room is usually determined by empirical rules based on practical results, which vary somewhat with different makers' and users' experience and give the following averages:

Capacity of Cold Rooms in Cu. Ft.	Temperature. Length of 1¼ in. Piping to be fixed in Stores.	
	30° to 35° F.	10° to 15° F.
1,000	225	450
10,000	1,125	2,250
100,000	6,000	12,000

Where other sizes of piping are used, the length is adjusted to provide a similar surface.

Calcium Brine.

Calcium Chloride Brine of a density ranging from 1·18 to 1·25 is usually employed. In estimating the weight of calcium chloride required to produce brine of a given density regard must be had to the fact that the commercial calcium chloride contains a large amount of water of crystallisation. An approximate rule is to multiply the density by 20 and subtract 20·1, the remainder gives the number of pounds of commercial calcium chloride required for each gallon of brine of the required density; for example, take the required density at 1·20, then $1{\cdot}20 \times 20 - 20{\cdot}1 = 24 - 20{\cdot}1 = 3{\cdot}9$ lbs. per gallon of brine.

Corrosion by Brines.

An important problem of refrigeration engineers is the corrosion by brines, either sodium chloride or calcium chloride, of copper, steel, or grey cast iron. An investigation by a French authority, M. Pierre, shows that the active element of this corrosion is due to the formation of an electrolytic couple, due to the association of air, brine, and the metal, and thus the dissolution of air should be avoided by submerging the return brine pipe so that it delivers below the level of the fluid in the main container. Strong brines cause more rapid corrosion, and the presence of magnesium chloride increases the activity. Lime or soda should be used with them to neutralise the formation of hydrochloric acid.

Insulation.

The thermal conductivity of the materials used for insulation may vary to some extent with individual samples, and with all loose fillings with the density to which they are packed.

The following figures are taken from the tests made at the National Physical Laboratory for the Food Investigation Board:

Material.	Density in lbs. per cu. ft.	Conductivity in B.Th.U.'s per hour per sq. ft. per 1 in. thickness and 1° F. difference in temperature.
Cork slab	11·3	0·306
" "	12·5	0·331
Granulated cork, fine	—	0·298
" " coarse	5·3	0·326
" "	7·3	0·345
Silicate cotton	13·0	0·302
" "	21·0	0·290
Dry charcoal	11·5	0·370
Kieselguhr	30·0	0·560
Wood—Pitch pine	42·0	1·036
Concrete	—	8·200

These figures are taken at normal cold storage temperatures. The conductivity increases slightly with an increase in temperature.

To obtain the conductivity of a compound wall, the reciprocals of the conductivities of its components must be added together, and this will give the reciprocal of the whole.

Thus, if a 6-in. concrete wall is insulated with 4-in. compressed cork slabs, the reciprocal of its conductivity

$$= \frac{1}{8 \cdot 2} \times 6 + \frac{1}{0 \cdot 33} \times 4 = 12 \cdot 85;$$

and its conductivity

$$= \frac{1}{12 \cdot 85} = 0 \cdot 078.$$

If, therefore, there is a difference in temperature of 40° F., the heat leakage would be 3·12 B.Th.U.'s per sq. ft. per hour, or about 75 B.Th.U.'s per sq. ft. per day.

It is not advisable to attempt to make any allowance for the rate of heat transfer between the air and the two wall surfaces, as while this may vary very greatly, it is in any case so relatively small an item that it does not appreciably affect the result.

In an insulated wall, the jointing material for cork slabs, the timber studding for loose fillers, and unavoidable inperfections of workmanship will make the conductivity of the material as erected rather greater than the test figures given, and the results should be increased by 10 per cent. to 15 per cent. to allow for this.

The leakage of heat through the insulated walls, floor, and ceiling of a cold store practically always forms the greater proportion of the total refrigerating power required to cool it, so it is necessary that the insulation provided should reduce this leakage to a minimum.

The first essential is that the material used should have a low co-efficient for the transfer of heat; it should have no attraction for moisture, be uninflammable, inodorous, and have a high specific heat.

It should pack well without tendency to settle and leave void spaces, and it should have no tendency to spontaneous combustion under any conditions.

Compressed cork slabs erected in cement or bitumen, and having their surfaces finished in hard-setting cement, provide the most satisfactory and permanent construction, but granulated cork and silicate cotton, or slag wool, are also largely used, and other materials that are employed are pumice stone, charcoal, kieselguhr, sawdust, and shavings.

Loose filling materials are packed between wooden studs and joists, erected against walls, floors, and ceilings, and covered by T. & G. boarding with or without waterproof paper.

An air space is often provided against external walls, the construction then being illustrated in figs. 4, 5, and 6.

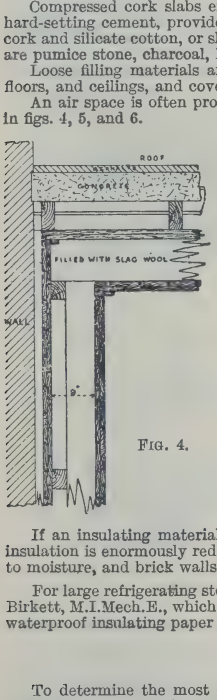


FIG. 4.

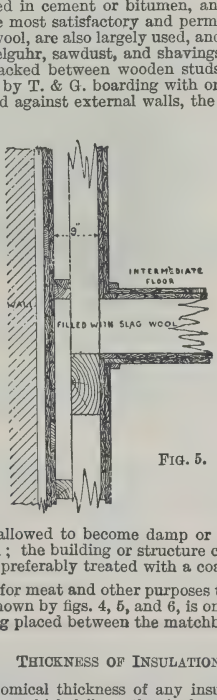

FIG. 5.

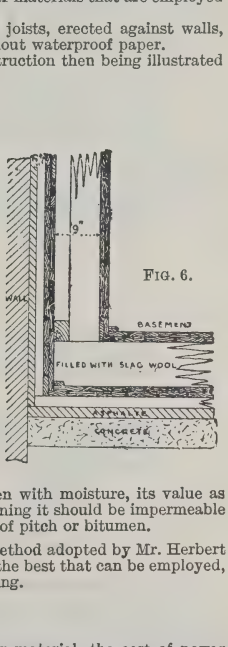

FIG. 6.

If an insulating material is allowed to become damp or sodden with moisture, its value as insulation is enormously reduced; the building or structure containing it should be impermeable to moisture, and brick walls are preferably treated with a coating of pitch or bitumen.

For large refrigerating stores for meat and other purposes the method adopted by Mr. Herbert Birkett, M.I.Mech.E., which is shown by figs. 4, 5, and 6, is one of the best that can be employed, waterproof insulating paper being placed between the matchboarding.

THICKNESS OF INSULATION.

To determine the most economical thickness of any insulating material, the cost of power to drive the refrigerating machine, which falls as the thickness of insulation increases, should be balanced against the interest on the increasing cost, and the decrease in the net or useful storage capacity.

The usual practice is to use a thickness of 4 ins. of compressed cork slabs for chill, and 6 ins. for freezing temperatures, or, alternatively, 6 and 9 ins. of granulated cork or silicate cotton. These figures are largely worked to, not entirely as giving equal insulating value, but as economical standards for the commercial thickness of cork slabs and sizes of timber.

Paper Insulation.

(*The Willesden Paper and Canvas Works, Ltd., Willesden Junction, London, N.W. 10.*)

A special description of paper known as 'Willesden' paper has for many years been largely used in the insulation of cold storage chambers. The usual method of constructing these chambers is to erect vertical studding at certain distances apart, and to cover this on both sides with grooved and tongued matched boarding, then to cover that in its turn with the Willesden paper, and over the paper to again fix another surface of matched boarding. There is then left a space between the two erections of matched boarding and paper equal to the width of the studding used, and this space is filled with some insulating material, such as charcoal, slag wool or rice husks, etc., and the work is done. The main use of the paper is to exclude air, and the Willesden material is preferred because of its durability and strength, and because it is not affected by damp nor liable to harbour fungoid growth.

'Neponset,' 'Ko-sat,' and 'Coted' are special papers of the highest grade, which are impervious to air and moisture under the severest conditions, and are largely used for cold storage insulation. They are made in rolls 36 ins. wide containing 1,000 sq. ft.

Cork Insulation.

The application of compressed cork slabs for insulation purposes is becoming more general, both in the U.S. and in England. Being in the form of slabs which are manufactured in various shapes and dimensions, they are easily fitted to the walls of the chamber. By being built together in various layers, breaking joint and cemented with a waterproof cement, they form an impermeable insulating lining to the chamber.

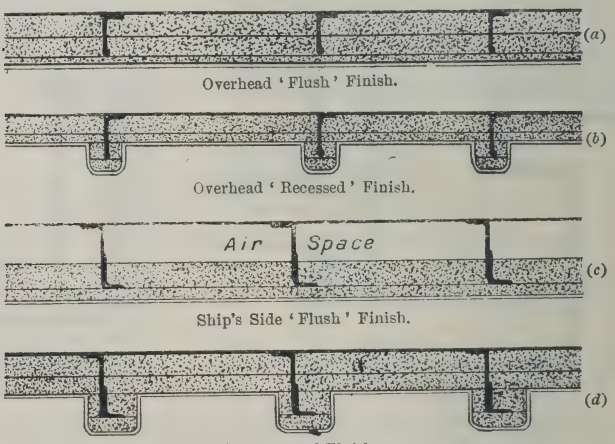

Fig. 7.—'Anderson' Jointless Insulation on Cork Slabs.

The interior facing to the chamber is usually of a special cement, preferably without joint.

With this system of insulation (fig. 7) a less thickness is required as compared with the insulating materials of a loose granular nature, and it has the further advantage of giving an increased capacity to the chamber. *Messrs. Thomas Anderson Ltd., Liverpool*, have had considerable success in its application. The efficacy of their preparation is illustrated by a recent case in which the insulation of a steamship, which had been submerged for weeks, on being raised was found intact, not requiring renewal or repair.

The material '*Fosalsil*' (p. 435) is very suitable for insulation purposes.

Insulation on Board Ship.

The insulation of cold chambers on board ship follows the same general principles and method that apply to insulation work carried out on land.

Owing to the way in which the ship's side and deck beams break up the surfaces, and to the absence of pure rectangular spaces, cork slabs are not so simple to use as loose filling

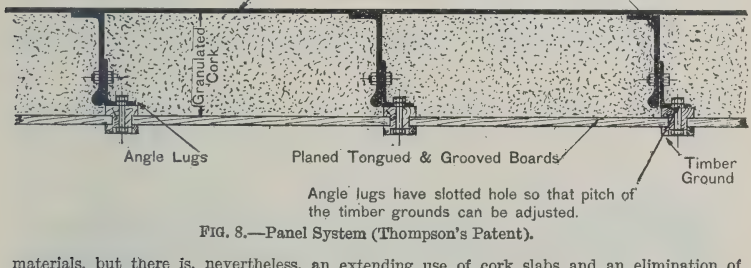

FIG. 8.—Panel System (Thompson's Patent).

materials, but there is, nevertheless, an extending use of cork slabs and an elimination of woodwork, inner linings, and air spaces.

One of the latest methods is the panel system of insulation (Thompson's patents), which, while it is particularly adapted to ships, is also applicable to work on land.

The construction is shown by figs. 8 and 9, and the advantages claimed are:

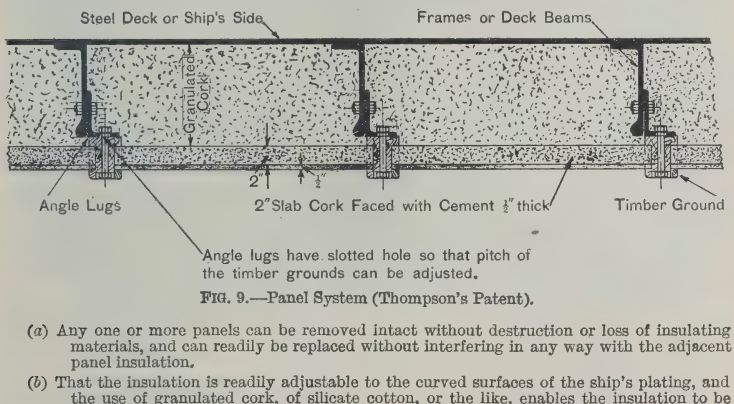

FIG. 9.—Panel System (Thompson's Patent).

(*a*) Any one or more panels can be removed intact without destruction or loss of insulating materials, and can readily be replaced without interfering in any way with the adjacent panel insulation.

(*b*) That the insulation is readily adjustable to the curved surfaces of the ship's plating, and the use of granulated cork, of silicate cotton, or the like, enables the insulation to be thoroughly well packed, no matter how curved or cut up the surface.

(*c*) When cement-faced cork slabs are used, the size of each slab being comparatively small, the liability to surface crack is slight.

(*d*) The wood grounds are exposed on the front faces, their condition can always be examined, and as they are ventilated, the danger of dry rot is greatly reduced.

(*e*) Repairs are easily effected, each panel being separate from all the others.

Operating Refrigerating Machinery.

As refrigerating machinery is solely concerned with temperatures, the gauges connected to the compressor suction and delivery are marked both with a pressure scale and a scale of the equivalent temperatures. The temperature scale should be used for regulating the working of the machine and in making any logs or records, as the differences are then obtained direct without reference to tables of properties.

The gauge on the suction side of the compressor indicates the pressure and temperature of evaporation, and that on the delivery side the pressure and temperature of condensation.

To operate a plant successfully, or analyse its working, it is also necessary to have thermometers to show the temperatures of:

1. The suction gas returning to the compressor from each separate evaporator circuit.
2. The discharge gas leaving the compressor.
3. The liquid refrigerant leaving the condenser.
4. The liquid refrigerant immediately before the regulating valves.
5. The brine leaving the evaporator.
6. The brine returning to the evaporator from each separate brine circuit.
7. The water entering the condenser.
8. The water leaving the condenser.
9. The temperature of the cold storage rooms, or, where a machine is used for special purposes, the temperature of the materials that are cooled.

The first four of these points are frequently omitted in commercial plants, but the second four are essential.

The suction gas thermometer readings should coincide with the evaporator gauge readings unless the suction gas is superheated, and thermometers in this position are particularly useful where there are several separate expansion circuits, as they provide the best indication for the quantity of liquid to be admitted to each, and for the manipulation of the regulating valves.

The discharge gas thermometer readings will be above the condenser gauge readings unless the compressor is run wet compression, and the elevation of the thermometer above the gauge temperature is an index of the dryness of the gas returning to the compressor.

The temperature of the liquid refrigerant will coincide with the condenser gauge reading unless the liquid is sub-cooled either by the use of a counter-current condenser or separate liquid cooler.

Sub-cooling of the liquid, particularly with CO_2, is always an advantage where it is practicable.

The regulation of the quantity of brine flowing through the separate circuits, and consequently of the refrigerating effect, is controlled by the difference between the brine flow and return temperatures.

The quantity of water flowing through the condenser is regulated by the difference in temperature between the inlet and outlet.

It is most important that the machine should be maintained fully charged with its refrigerant, and that supplies should be added from time to time to make good the inevitable small losses that occur with even the most carefully operated plant.

With a proper charge and well-proportioned installation, the condensing temperature should be from 10° to 15° F. above the mean condensing water temperature, and the evaporating temperature from 10° to 15° F. below the mean temperature of the brine, or about 15° to 20° F. below the air temperature when cold storage rooms are cooled by the direct expansion system.

At the same time the suction valve ports on the compressor should be frosted over, and, in the absence of thermometers, the delivery should be as hot as the hand can comfortably bear.

Closing down the regulating valve reduces the evaporating temperature and increases the gas discharge temperature, while opening up the regulating valve increases the evaporating temperature and decreases the discharge gas temperature.

The dryness of the suction gas is indicated by the discharge gas temperature, and while the aim should be to work as nearly as possible dry compression, the conditions of working that best suit individual makes of compressors and proportions of plant can only be determined by experience with them.

An undercharge of refrigerant is indicated by a high delivery temperature, a low condensing gauge temperature, and a low evaporator temperature, which does not rise as it should when the regulating valve is opened.

An overcharge is indicated by a cold delivery temperature, a high condenser gauge temperature, and an evaporator temperature which does not fall at the normal rate when the regulating valve is closed.

Of the two, an undercharge is the more serious, as it results in a reduced refrigerating effect, while an overcharge practically only affects the power required.

The refrigerant should be kept in pure condition by occasionally purging out any air or foreign gases, and the oil separator should be regularly drained to prevent oil passing over into the condenser and evaporator.

Refrigeration on Board Ship.

The use of refrigerating machinery on board ship may be roughly subdivided into three groups:

I. Small plants to cool provision storage rooms and to make small quantities of ice.

II. Large passenger vessels that are arranged to carry refrigerated cargo.

III. Large vessels used primarily for refrigerated cargo.

CO_2 refrigerating machines are almost invariably used for all classes and sizes of machines, and evaporative liquid cooling of the CO_2 is frequently employed.

On steamships the larger machines are practically always steam-driven and incorporate their own steam condensers, but the smaller machines are now generally driven by electric motors, and on motor ships an electric drive is always used.

Compressors running at low and medium speeds are generally preferred, and while direct-coupled sets are sometimes installed, the drive is generally through double helical or other speed-reduction gears.

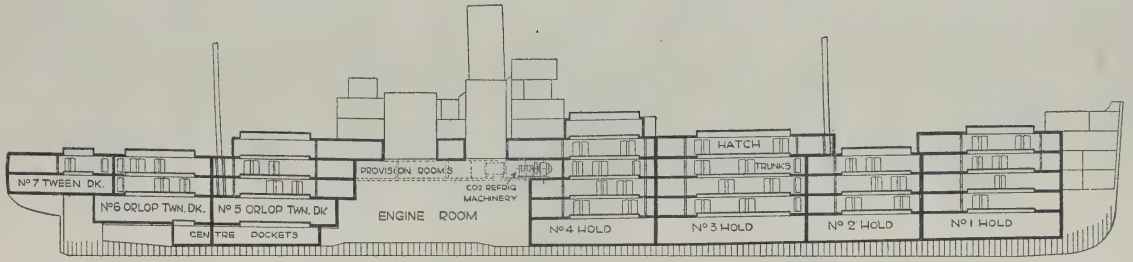

FIG. 10.

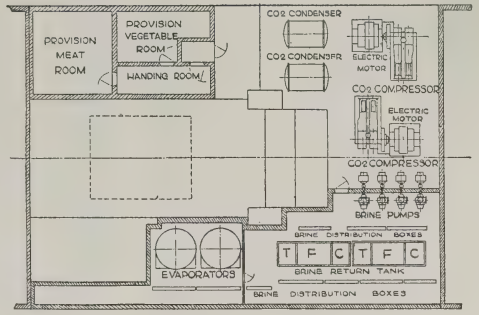

FIG. 11.

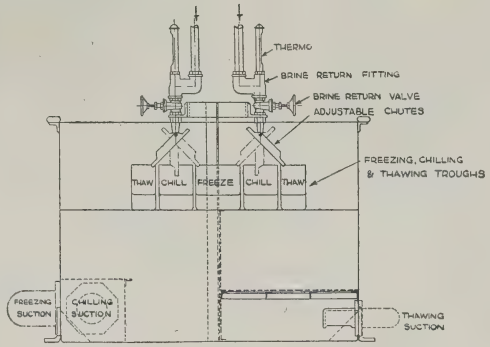

FIG. 12.

The third group includes the increasing numbers of vessels used solely for the carriage of tropical fruits, but by far the most valuable and important marine installations are those intended mainly for the carriage of chilled beef.

Some of these have an insulated capacity of upwards of 600,000 cu. ft., and a typical section of such a vessel, together with the arrangement of the refrigerating machinery supplied by *J. & E. Hall, Ltd.*, is shown in figs. 10, 11, and 12.

In these vessels both chilled and frozen meat can be carried, and the insulated spaces are cooled by piping in them through which cold brine is circulated.

The brine pipes are arranged in a number of circuits of limited length so that the return temperatures shall only show a small rise, and each of these circuits is separately controlled.

In modern practice a number of the spaces are, in many cases, also provided with air-cooling batteries and fans, so that cold air circulation can be used either to supplement the brine piping or as a complete alternative.

The method of cooling by cold air circulation is often preferred for fruit and for other cargoes that are carried at a temperature above the freezing-point.

The carriage of chilled beef calls for very precise regulation of the temperatures to be maintained in the various spaces.

This is effected by what is known as the three-temperature brine system, with mains providing for the delivery of brine at suitable temperatures for freezing, chilling, and thawing service, to enable any temperature from freezing to chilling to be maintained in the various spaces to suit the class of produce carried, and individual requirements of shippers.

The great majority of the large meat-carrying installations are arranged on the open brine circulating system, but the closed system is preferred by several important shipowners.

Both systems have certain advantages; both produce excellent results in practice, and the balance between them may be said to be a matter of individual preference.

The general principle common to both systems is that the brine returning from the piping in the chill spaces is pumped directly back to the chilling delivery header, but the heat absorbed by the brine in its passage through the chilling circuits is eliminated by means of an injection of the freezing brine into the chilling system, there being a corresponding overflow to the freezing system.

When carrying mixed cargoes, it is often an advantage to run one of the evaporators at the chilling and the other at the freezing temperature, instead of having both on the low temperature, and to use the system of brine injection, or attemperating, as it is often termed.

In the open system the brine returns into an open return tank or tanks placed in an insulated space adjoining the machine room, which also contains the headers, valves, cocks, and thermometers required to control the flow of brine.

The arrangement is shown in figs. 11 and 12, and the detailed arrangement of the piping for the same vessel in fig. 13.

An example of the closed brine system is shown diagrammatically in fig. 14, p. 1228, for a vessel fitted up by the *Liverpool Refrigeration Co., Ltd.*

Figs. 15 and 16 (p. 1229) show the form of main attemperating valve and attemperating cock of the Liverpool Refrigeration Co., Ltd.; these, as will be seen, adjust the proportion of chilled or cold brine in such a manner that the one supply is cut off in proportion to the amount the other is opened up.

The flow of brine through the circuits is sometimes controlled by flowmeters placed in them. In other cases no special arrangements are made for measuring quantities, and the control is made entirely on the thermometer readings, but each return has a bye-pass connection, so that the brine may be diverted into an open tank for testing purposes if required.

A large modern installation may involve up to about 200 separate brine circuits, and the control room for a closed brine system fitted up by the *Haslam Foundry & Engineering Company* is shown in fig. 17 (p. 1230).

The refrigerating machinery for these installations always consists of at least two units, each complete with its condenser and evaporator, and capable of independent working, each being of sufficient capacity to maintain the required temperatures in the cargo spaces at sea if the other is out of action.

In some important cases there are three machines, two of which have ample power to maintain the cargo with one independent unit in reserve.

The machines are often of the Duplex type, with a cross compound engine driving the CO_2 compressors from the tail rods, and arranged so that either side can be used independently. Large single machines are made with tandem compound steam cylinders driving one compressor direct.

There are also a few examples of triple compressor machines with three-cylinder engines, as shown in fig. 18 (p. 1231), illustrating an installation by the *Liverpool Refrigeration Co., Ltd.*

The CO_2 condensers are constructed of solid drawn copper piping contained in cast-iron casings. The evaporators are generally of solid drawn steel piping contained in built steel casings, and in modern practice both brine and water circulating pumps are of the centrifugal type direct coupled to electric motors.

The pump connections to the suction and delivery mains are made to valve boxes, permitting an interchange of duties on the respective chilling and freezing circuits, and for one pump being always available as a standby for either duty.

Water Coolers.

The 'Heenan' Patent Water Cooler.

The latest type of cooler recently introduced by Messrs. Heenan & Froude, Ltd., Worcester, claims a minimum consumption of water per brake horse-power-hour, and has the advantage of being compact and occupying comparatively small space. The apparatus is also self-contained. It is of the stationary type, and has no moving parts beyond the fan which circulates the air, and the pump which circulates the water.

The apparatus (as shown by fig. 19) consists of an outer casing, which is rectangular in shape, built up of mild steel plates. The base of this casing forms a tank into which the water drains after cooling, and previous to re-circulation.

The cooling effect is obtained by evenly distributing the heated water over a number of screens set up one above the other in the body of the cooler.

The water to be cooled, after passing through a strainer, enters at the top of the cooler and falls on to the screens through nozzles which feed perforated troughs. In its fall through the screens it meets a current of cold air which is forced upward through the casing by a centrifugal fan, the discharge from which is introduced to the underside of the lowest screen.

The screens are formed of phosphor-bronze metallic wool of standard size and thickness, held together between wire netting which is attached to angle-steel frames.

The cooling effect is positive and continuous, the cooling surface being always efficient, and the volume of air being a predetermined quantity which is not dependent on climatic conditions. By suitably proportioning the size of the machine for the duty which it has to undertake, water can be cooled down to a temperature closely approaching that of the prevailing wet bulb thermometer. Thus in hot weather—in temperate as well as in tropical climates—re-cooled water can be provided at a temperature considerably below the dry bulb temperature of the surrounding atmosphere. This feature renders the machine especially suitable for dealing with the circulating water of refrigerating plants, for which purpose large numbers of 'Heenan' coolers have been supplied. The practical value of the cooler is due not only to the saving in water but to the improved efficiency of the refrigerating plant, resulting in lower compression pressures and reduced power consumption.

'Pulsometer' Refrigerating Plants.

The Pulsometer Engineering Co., Ltd., are manufacturers of apparatus for working on both the NH_3 (Ammonia), and CO_2 (Carbon Dioxide) compression systems, and their machines are designed and manufactured on the principle that high efficiency as well as reliable and satisfactory service with a minimum amount of attention is of first importance, and apart from the large number of plants of various capacities they supply for land service both in this country and most countries abroad, they are large suppliers of marine type plants for ordinary ships' stores cooling and icemaking, and also for magazine cooling, refrigerating, and icemaking on board war vessels.

A considerable number of cargo and passenger boats have been equipped with this type, and the manufacturers have recently developed an improved design in the form of an enclosed type quick running splash lubrication machine which is particularly suited for both land and marine use. Though marked by many up-to-date improvements, it retains most of the features for which the early designs were so well known, i.e. simplicity and ease of operation with the minimum amount of attention, freedom from breakdown, and low cost of maintenance.

Negretti & Zambra's Low Temperature Electrical Distance Thermometer.

This Thermometer (which depends upon the variation of an electrical resistance by change of temperature) is specially designed for cold-storage work suitable for dairies, butter factories, and meat storage.

The advantage of its installation is that it is possible to read in a central position the temperatures of a number of different points situated some distance away, i.e. the temperatures of cold chambers can be read in the engine room or the manager's office, which is a great advantage and assists the economical working of the plant.

The elements or thermometer bulbs are placed in the cold chambers, brine pipes, etc., and connected up to the indicator by means of lead-covered wire, the electric current being provided by an accumulator. These elements vary according to the purpose for which they are required, either for air temperatures, or for brine or water temperatures.

THE 'HEENAN' PATENT COOLER. TYPE 'V.'

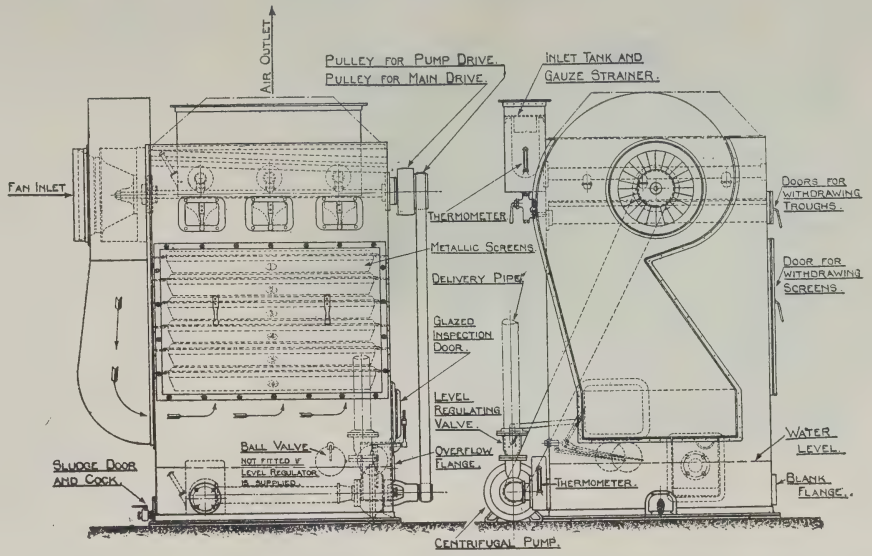

FIG. 19.

The indicator (fig. 20) is mounted in a cast-iron moisture-proof case sprayed and stoved white, the scale being graduated to cover the temperatures required, such as cold stores – 20 to + 100° F., etc. There is a multiple point switchboard incorporated in the case, by means of which the temperature of any point can be read on the indicator as desired.

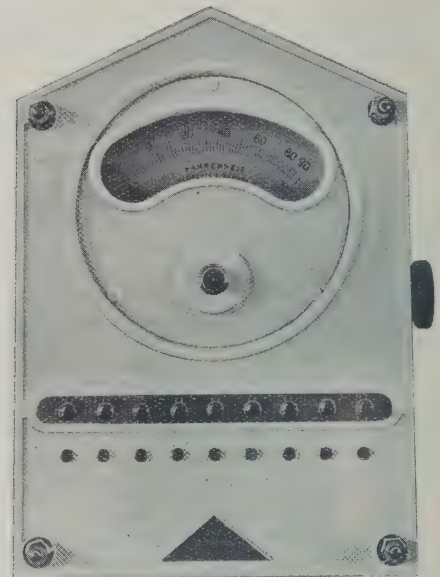

FIG. 20.

All the connections are enclosed in the case, so that they are adequately protected from moisture, dust, etc.

The connecting wire used is a 3-core cable, lead-covered for protection.

LLOYD'S RULES FOR THE SURVEY OF REFRIGERATING MACHINERY AND APPLIANCES OF FROZEN MEAT STORES.

(Abstract.)

Power of Machinery.—The refrigerating machinery is to be of approved construction and of sufficient power to maintain a temperature of 15° F. simultaneously in all insulated chambers when running 18 hours per day.

Motive Power.—Each compressor is to be driven by independent means, or, alternatively, the motive power is to be in duplicate.

Where the compressors are electrically driven, a spare electric generator is to be fitted, unless the power is supplied by a public generating station.

Where electric transformers are installed on the premises, a spare transformer is to be fitted.

Hydraulic and other Tests.—In the case of new refrigerating machinery and appliances, the tests recommended for the various parts are as follows, viz.:

(*a*) CO_2 compressors, separators, condenser and evaporator coils, headers and connections to be tested by hydraulic pressure to 3,000 lbs. per sq. in., and afterwards by air pressure to 1,500 lbs. per sq. in., whilst submerged in water.

(*b*) NH_3 compressors and cast iron or steel connections to be tested by hydraulic pressure to 600 lbs. per sq. in. Where compound compressors are fitted, the low pressure compressor and cast-iron or steel connections to be tested by hydraulic pressure to 200 lbs. per sq. in.

(*c*) NH_3 condenser, evaporator and air cooler coils to be tested by hydraulic pressure to 1,500 lbs. per sq. in., and afterwards by air pressure to 500 lbs. per sq. in., preferably whilst submerged in water.

(*d*) NH_3 plant, after erection in place, to be tested by air pressure; the gas delivery side (*i.e.* from the compressor to the liquid expansion valves) to 200 lbs., and the return side, including the direct expansion piping for the chambers (*i.e.* from the liquid expansion valves to the compressor suction valves) to 150 lbs. per sq. in.

(*e*) Brine piping, after erection in place, to be tested by air or water pressure to 90 lbs. per sq. in.

(*f*) Gas evaporator casings of cast iron and gas condenser casings, whether of cast iron or steel, where of enclosed type, to be tested by hydraulic pressure to 15 lbs. per sq. in., or to double the working pressure, whichever is the greater.

(*g*) Gas evaporator wrought-iron and steel casings, where of enclosed type, to be tested by hydraulic pressure to 30 lbs., if gravitation type, or to 50 lbs. per sq. in. if pressure type, or to double the working pressure, whichever is the greater.

Cooling Tests.—(*a*) Upon completion of the installation under special survey, the refrigerating machinery is to be tested under working conditions, and the insulated chambers are to be cooled down simultaneously to about 15° F.

(*b*) The whole of the refrigerating power may be used in order to reduce the temperature, but the specified temperature is to be maintained in the insulated chambers for a period of 12 hours with the spare compressor unit out of action.

Brine Cooling System.—(*a*) Where the brine system of refrigeration is employed the cooling pipes in each refrigerated chamber of over 5,000 cu. ft. capacity are to be arranged in not less than two sections, and the cooling surface is to be sufficient to maintain the working temperature of the chamber when one of the sections is out of use. Isolating valves or cocks are to be fitted to each section of cooling pipes.

(*b*) The brine circulating pipes and brine tanks should not be galvanised on the inside.

(*c*) In cases where internally galvanised tanks or cooling pipes are fitted, the brine cooling and return tanks, if of closed type, are each to be provided with a ventilating pipe or pipes led to the open air in a situation where no danger will be incurred from the issuing gas, and each ventilating pipe is to be fitted with a wire gauze diaphragm which can easily be removed for renewal.

(*d*) Where the tanks are not closed the compartments in which they are situated are to be efficiently ventilated.

Direct Expansion System.—Where the direct expansion system of refrigeration is employed, the cooling pipes in each refrigerated chamber of over 5,000 cu. ft. capacity are to be arranged in not less than two sections, and the cooling surface is to be sufficient to maintain the working temperature of the chamber when one of the sections is out of use. An expansion valve and a return gas valve or cock are to be fitted to each section of cooling pipes.

PART I

HYDRAULICS—GENERAL DATA OF WATER—WATER PRESSURE—HORSE POWER REQUIRED TO PUMP WATER—PRESSURE IN HYDRAULIC MAINS—DIMENSIONS AND STRENGTH OF HYDRAULIC PIPES AND CYLINDERS—PIPE UNIONS AND JOINTS.

General Data Regarding Water.

An imperial gallon of water at 62° F. weighs 10 lbs. avoirdupois. (See also page 124.)

Gallons × 277·420 = cu. ins. (*International Bureau of Standards, Paris*, 1921.)

Gallons × 0·16055 = cu. ft.
Cu. ft. × 6·2288 = gallons.
Cu. in. × 0·0036047 = gallons.
Cu. ft. × 62·288 = lbs. weight.
Lbs. × 0·016053 = cu. ft.

Gallons × 0·004464 = tons.
Tons × 224 = gallons.
Cu. ft. × 0·027807 = tons.
Tons × 35·962 = cu. ft.

A pipe one yard long holds approximately (actually, 1·52 per cent. less) as many lbs. of water as the square of its diameter in inches; thus, a 6-inch pipe holds approximately 36 lbs. of water in each yard length.

VISCOSITY (ν)* OF WATER IN C.G.S. UNITS AT VARIOUS TEMPERATURES.

(Calculated from data in *The Philosophical Transactions of the Royal Society*, A., Vol. 214.—*H. R. K.*)

C.°	8·6	10·2	10·5	10·7	11·1	11·3	11·5	14·3	15·0	16·0	20·5	23·0	25·0
F.°	47·5	50·4	50·9	51·3	51·9	52·3	52·7	57·7	59·0	60·8	68·9	73·4	77·0
ν	0·0136	0·0131	0·0130	0·0129	0·0128	0·0127	0·0126	0·0115	0·0114	0·0110	0·0100	0·0093	0·0090

(Approximately the viscosity at 69° F. is 0·01. The viscosity varies approximately 2·06 per cent. for each C.°, or 1·2 per cent. for each F.°

Water-Pressure.

If

H = head of water in feet; P = lbs. pressure per square inch,

$$H = P \times 2{\cdot}311. \qquad P = H \times {\cdot}4326.$$

10 feet head of water gives a pressure of 4½ lbs. per square inch, approximately,

27·71 inches of water gives a pressure of 1 lb. per square inch.

* See note p. 994.

(H. R. Kempe.)

Horse-power required to Pump Water.

1 H.P. indicated will raise about 3,000 gallons of water per hour 50 feet high.

To pump 1 gallon of water per minute against a pressure of p lbs. per square inch requires $p \times \cdot0007$ H.P.

Allowing 40 per cent. for friction, the following shows the H.P. required to pump 1 gallon of water per minute at various pressures :—

Pressure per square inch, in lbs.	500	700	1000	1200	1500	2000	2250	2500	5000
Horse-power	·49	·69	·98	1·18	1·47	1·96	2·21	2·45	4·90

The *cost of lifting* 1 ton 50 feet is, in the case of the London Hydraulic Power Company, sometimes as low as $\frac{1}{4}d$.

Speed of Water should not, as a rule, exceed 100 feet per minute with 700 lbs. pressure. In the mains of the London Hydraulic Power Company the delivery is 1,040 gallons per minute, at a velocity averaging 2·83 feet per second, or 170 feet per minute. The loss of head due to this velocity is 22·896 feet per 1,000 yards, by the formula :—

$$\frac{(\text{Gallons per minute})^2 \times (\text{length of pipe in yards})}{(3 \times \text{diameter of pipe in inches})^5}.$$

The most distant point of the main is 5,320 yards, or just over 3 miles, from the accumulators. In a circuit of 5 miles the normal difference of pressure, or loss of head, was 20 feet head.

Pressure in Hydraulic Mains.

The average working pressure is 700 lbs. per square inch with accumulators, but varies from 300 to 1,500 lbs. per square inch. The pressure in the mains of the London Hydraulic Power Company averages 700 lbs., the actual pressure at the accumulators being 750 lbs.

700 lbs. per square inch = 549·78 lbs. per circular inch, equivalent to a head of 1,618 feet.

Number of threads per inch . .	14	14	14	11	11	11	11	11	11	11	11							

(1)

The external diameter, D, may be calculated from the formula :—

$$D = d\left(\frac{p}{f} + 1\right),$$

where,

d = diameter of bore of pipe, in inches ; p = pressure, in lbs., per square inch ; f = 4,000 for wrought iron, and 1,200 for cast iron.

(2)

$$T = \frac{(P + 100)\,D}{0{\cdot}4\,S} + 0{\cdot}333\left(1 - \frac{D}{100}\right),$$

where,

T = thickness of pipe in ins.; D = interior diameter of pipe in ins.; P = pressure of water in lbs. per sq. in.; S = ultimate tensile strength of cast-iron in lbs. per sq. in. (taken as 18,000 lbs.).

This formula gives the weight and thickness for good, tough, and elastic cast-iron pipes covering the ordinary range of static pressures of public water supplies.

60	1·35	1·50	1·70	—	—

(*R. D. Wood & Co., America.*)

(3)

$$T = \frac{(P + L)\,R}{3{,}300} + 0{\cdot}25.$$

where

T = thickness of pipe in ins.; P = static pressure in lbs. per sq. in.; R = inside radius of pipe in ins.; L = pressure in lbs. allowed for water hammer; 0·25 = a constant allowance for inequality in manufacture, deterioration, and rough handling; 3,300 = one-fifth of the tensile strength of cast-iron, which is taken to be 16,500.

The values of L—the allowance for water hammer—for different sizes of pipe are as follows, the allowance decreasing as the diameter and thickness of pipe increase :—

Diameter of Pipe, Ins.	Value of 'L,' Lbs.	Corresponding Head, Ft.
3, 4, 6, 8, or 10	120	277
12 or 14	110	254
16 or 18	100	231
20	90	208
24	85	196
30	80	185
36	75	173
42, 48, 54 or 60	70	162

For a static pressure of 100 lbs. per sq. in. a 6 in. pipe need be only 0·10 in. thick. Such thin pipe, however, could not well be made or handled, and allowance must be made (as above) for shock due to water hammer, for roughness in handling, for inequality in manufacture, and for deterioration. (*D. Fitzgerald, America.*)

Thickness of Hydraulic Cylinders.

If T = thickness of metal in inches, P = bursting pressure in lbs. per square inch, R = radius of cylinder in inches, and C = constant (16,000 for cast iron, 34,000 for brass, 50,000 for wrought iron, and 70,000 for steel),

$$T = \frac{PR}{C - P}.$$

If D = external diameter of cylinder in inches, and d = internal diameter in inches, P and C being as above, then

$$D = d\sqrt{\frac{C + P}{C - P}}.$$

Strength of Hydraulic Cylinders.

If f = allowable stress in lbs. per sq. in.; P = working pressure in lbs. per sq. in.; d = inside diameter in ins.; D = outside diameter in ins.; then

$$D = d \times \text{anti-log}\left(\frac{P}{p} \cdot 4343\right). \qquad \textit{(Clark.)}$$

EXAMPLE.—If P = 3,000 lbs. per sq. in.; f = 8,000 lbs. per sq. in.; d = 30 ins.; then

$$\frac{P}{p} \cdot 4343 = \frac{3,000}{8,000} \cdot 4343 = \cdot 16286$$

anti-log.* of ·16286 = 1·455 (page 99);

therefore $D = 30 \times 1 \cdot 455 = 43 \cdot 65$ ins.

Size of Hydraulic Mains.

The largest mains used for hydraulic purposes are 7½ inches in diameter. The working stress on the metal due to working pressure is 2,800 lbs. per square inch. The mains are usually tested to a water-pressure of 2,500 lbs. per square inch before laying, and to a pressure of 800 to 1,600 lbs. per square inch after laying.

Pipe Unions and Joints.

For wrought-iron pipes up to 2 inches in diameter, such as are used for the connecting-pipes to hydraulic machines, the unions are generally of brass, and of the form shown by fig. 1. For

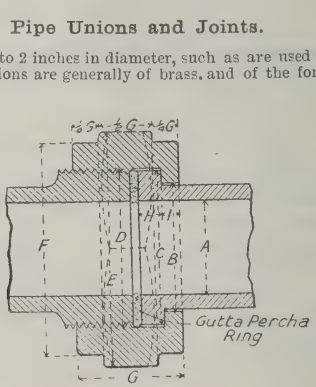

FIG. 1.

main cast-iron pipes the unions are made by means of elliptical flanges (fig. 1) formed on the ends of the pipes, the inner faces of the flanges being turned so that one pipe can enter a little distance into the other; a recess is left between them, to receive a gutta-percha ring, whose outside diameter is about 4 times the inner.

Mains fitted with flanged joints of the description shown by fig. 2 can be made absolutely tight and free from leakage. The flanges are placed in a horizontal position in laying.

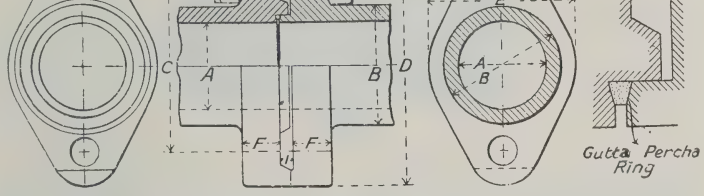

FIG. 2.

Mr. Ellington (engineer of the London Hydraulic Company) found that fractures in the pipes occurred by the breaking off of one of the bolt lugs. By placing the lugs a little farther back on the pipe the strength was found to be greater. It is probable that the slight flexibility of the pipe line which this kind of joint allows is an important element in its success.

On low-pressure hydraulic systems ordinary socket joints can be used.

In the *Philosophical Magazine* the Earl of Berkeley and Dr. Burton have described a simple form of joint packing, which is, they state, tight to start with and maintains this tightness up to the highest pressures they have employed, which have attained 1,500 atmospheres, or

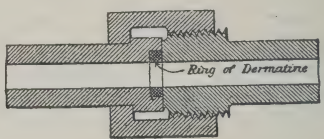

FIG. 3.

say, 10 tons per square inch. The pipe ends (fig. 3) are faced, and a recess is cut in one to take a ring of dermatine; this ring must be slightly thicker than the depth of the recess so that it is slightly compressed when the joint is tightened up. Either red or black dermatine may be used, but the red, being harder, is more easily machined. The joint is said to be equally good for water or oil, and is as suitable for a flanged joint as for a screwed coupling. It is also said to be as satisfactory with large pipes as with small.

THE 'VICTAULIC' SYSTEM OF FLEXIBLE PIPE LINES.

This system (fig. 4) employs pipes with shouldered ends, which are engaged with a certain amount of clearance by the split housing of the joint, which, while coupling the pipes together, permits disalignment or movement due to expansion of the pipes.

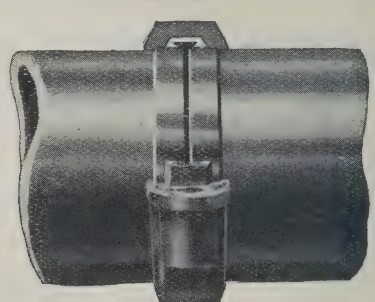

FIG. 4.

Within the split housing is a special design of double 'U' washer, which exercises an initial grip upon the pipe ends and is self-sealing as the pressure rises. By a special proportioning of the buttress-shaped walls of this leak-proof ring, the joint is also self-sealing against a vacuum.

A feature of the joint is its extreme ease in fitting, since there are only two bolts and the joint is not dependent for its tightness upon heavy mechanical pressure. The makers claim that the average time taken in fitting their 6-in. joints by unskilled labour is only two minutes.

The leak-proof ring, being of a fine quality rubber, is of a very durable nature; for oil or gases, acids, etc., a special mixture is used.

The joint is not supplied for use with steam.

Fittings, valves, etc., are all supplied with the ends shouldered or expanded in the same way as the pipe ends, and complete installations can be rapidly built up.

The dimensions of pipe ends are standardised by all the leading tube makers (see table on page 1169), so that all joints and tubes of the same nominal bore will match up together.

Cement Joints for Cast-Iron Water Mains

(1.)

The pipe is placed and spaced in the usual manner. A thin backing of the best dry jute is used instead of oakum, as the jute is free from oil and grease, which should be avoided. Portland cement is placed dry on a piece of canvas (usually a cement sack ripped open) and moistened so that when thoroughly mixed by hand it will be of such a consistency that when gripped tight it will take the form of the hand and when dropped 12 ins. will crumble. The canvas containing the cement is placed under the bell, and the cement tamped into place by hand with a caulking iron until the bell is about half full. It is then caulked with heavy blows until the cement is thoroughly packed in the back of the socket. The process is continued until the bell is packed solid out to the face. A small bead of neat cement is then put on (this is essential), the caulking iron being used as a trowel, and, as soon as the initial set of the cement in the bead has taken place, the joint is covered with earth to protect it from the air and sun. In back-filling the excavated material is always settled with water, which helps to cure the exposed portion of the joint. The joint is allowed to stand forty-eight hours before the pressure is turned on and the main put into service. At Long Beach, California, there are now sixty miles of cast-iron water mains, ranging from 4 ins. to 24 ins. in diameter, laid with joints of this type. All these pipes are under pressures ranging from 40 lbs. to 80 lbs. per sq. in., and are giving satisfaction.

(*Clark H. Shaw, the American Society of Civil Engineers.*)

(2.)

A method of cement jointing cast-iron water pipes is described by Mr. G. W. Pracy in the *Journal of the American Waterworks Association*. The spigot end of the pipe projects into the bell just the same as for a lead joint, and two rings of jute or yarn are placed round the pipe and driven into the bell in the regular manner. The jute used must be free from oil or tar. Neat cement of standard Portland cement brand is used. The mix is very dry, the proportions being about 13 lbs. to 14 lbs. of cement to 1 lb. of water. The operator takes a handful of cement, and with an ordinary caulking iron forces the cement into the joint until full. He then takes a caulking hammer and caulks the joint until the cement is rammed in as hard as possible. The joint is then again filled and the operation repeated until the joint is completely filled with the rammed cement. At first a bead was put around outside the bell, but this was discontinued as being unnecessary. After the joint is finished it is covered with earth while the cement is hardening. In one case over a mile of piping jointed in this manner has been in use under 175 lbs. per square inch pressure for more than two years without requiring any repairs. It is claimed the method is cheaper than lead joints, and one indirect advantage is that the cement joint is an insulating joint, which tends to reduce damage from electrolytic action.

Pipe Joints for Petrol.

Pipe joints for petrol at ordinary atmospheric temperatures can be made up tight by first filling between the screw threads of the pipe with a thin paste made of gum shellac dissolved in a 10 per cent. solution of ammonia. The screw threads of both pipe and fittings should be thoroughly cleaned of grease before application of the paste.

Concrete-Lined Metal Pipes.

It has been American practice for some years past to line metal pipes with a thin coating of cement, which usually does not exceed three-eighths of an inch in thickness, applied by brush, cement gun, or by hand tamping. The experience gained with such pipes, some of which have now been in continuous service over periods of eight to ten years, showed that no appreciable incrustation had taken place even with bad waters. The iron or steel pipe lined with cement was found to have the further advantage that the interior surface could be rendered perfectly smooth—making its coefficient of friction not appreciably different from that of a new cast-iron pipe.

Stanton Centrifugally Concrete-lined Pipes.

A rotary motion is imparted to the pipe by four friction wheels driven by chains and operated by a hand-controlled variable-speed motor. The pipe having been trued up, internal rings are placed in position in order to prevent the concrete coming out at the ends of the pipe during the spinning process. During the first spin the pipe is rotated slowly over a period of about ten minutes, during which time the sand and cement concrete is shovelled into each end of the pipe by hand. Owing to the centrifugal force the cement does not fall down, but adheres to the surface of the pipe, and further consolidation is effected by passing a 3-in. diameter rod with a bronze sleeve through the pipe and pressing this by hand against the revolving internal surface. After the correct thickness has been deposited the pipe is spun at a higher speed, which drives the coarser particles of the concrete towards the iron surface of the pipe and gradually expels the water and slurry from the internal surface. During the spin the water and slurry form a thin revolving film, which, as soon as the pipe is brought to rest, falls to the bottom of the pipe. The internal end rings are then removed and the water brushed out. The concrete lining is now quite hard, and after three or four weeks in the open the pipe is ready for service. In the larger pipes the lining is about $\frac{1}{2}$ in. in thickness, but it may be increased up to 1 in. or more if so desired.

Pipes from 4 ins. to 72 ins. diameter may be lined.

The concrete lining is so finished at the socket end that when the joint is made the water in the pipe is only in contact with concrete and does not touch the iron in any part.

A pipe may be drilled and tapped without the concrete unduly breaking away at the edges of the hole, while the operation of running and caulking the joint can be carried out without detrimental effect on the lining. The effect of exposure to the weather has been investigated by leaving a 48-in. diameter pipe in the open for two years, and although subjected to effect of sun and frost no alteration has been detected either in the metal or in the concrete. A modified form of construction is represented by a series of 60-in. diameter pipes made for the Birmingham Corporation. The shells of these pipes are made from $\frac{3}{8}$-in. steel plates bent and welded into a 5-ft. diameter circle. The steel tube is so light that when the finished shell is placed on the ground it takes up a more or less oval form, being distorted in diameter by nearly $\frac{3}{4}$ in. These tubes are filled with a concrete lining $1\frac{1}{2}$ in. in thickness, which, when formed by spinning, is sufficiently strong to prevent all distortion and give to the pipe a perfectly round shape.

The process of centrifugal lining has also been most successfully applied to the new spun cast-iron pipes which are being manufactured at Stanton in sizes from 4 ins. up to 15 ins. in diameter. The spun cast-iron pipe has not only the advantage that it is nearly 25 per cent. lighter than the ordinary vertical sand-cast pipe, but the way in which it is made ensures a perfectly round and true pipe, avoiding the necessity of re-truing before the lining process.

SECTION XXV

PART II

PUMPS — STEAM PUMPS — PUMP PACKING — CENTRIFUGAL PUMPS—TURBINE PUMPS—AIR LIFT PUMPS.

PUMPS.

The surface of the water to be raised should not be more than 25 feet below the movable valve.

Especially for small pumps, the suction pipe of a pump should fall all the way from the pump to the supply well. Any upward bend in the suction pipe introduces an air trap and may seriously diminish the performance of the pump.

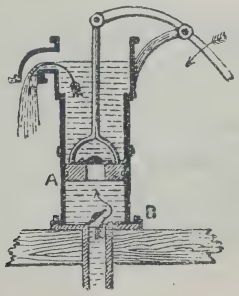

FIG. 1.

FIG. 2.

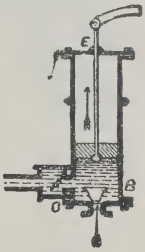

FIG. 3.

THE SUCTION PUMP.

This form of pump, which is shown by fig. 1. consists of a cylinder, called 'the barrel,' with valve, B, in which works a piston, A, called 'the box,' with valve in it, both valves opening upwards. The piston is attached to a rod and worked by a handle. When the handle is raised the piston is depressed: the valve A opens upwards, allowing the water or air below it to escape into upper part of cylinder. When the piston is raised the valve in it is closed, the water above is lifted up through the spout, the water from below lifts the valve at B, and rushes up to fill the vacuum caused by the raising of the piston.

If the valves are very dry a little oil should be poured on them. A little water poured on the piston before commencing to work it, makes it air-tight.

LIFTING PUMP.

The suction pump is converted into a lifting pump by attaching a pipe in place of a spout at C (fig. 2), with a valve in it, opening upwards to prevent the return of the water. A stuffing-box is provided for the piston-rod to work in at E. Each time the piston, A, is raised the water above it is forced up the pipe, and, as the piston descends, the valve C prevents the return of the water from above. It is clear that the man who pumps must exert at each upward stroke of the piston as much strength as is necessary not only to raise a cylinder full from below, but also to lift the column of water in the pipe above.

The valve C is not necessary to the action of the pump, because, the barrel being full, the valve B retains all the water. It is used more as an additional check. The pump would also act if only valve C were in and B removed.

Single-acting Force Pump.

This form of pump, shown by fig. 3, is used to force up water to a height. The piston is made without a valve. The delivery pipe is at bottom of piston: it has a valve opening upwards at C to prevent the return of the water. When the piston is raised the valve B opens and the water rushes into the cylinder: when the piston descends valve B closes, valve C opens, and the water is forced up the pipe. In this pump the force is required for the down stroke. The top of the cylinder E need not be closed; a little water poured in above the piston makes it air-tight.

Plunger Pump.

Sometimes a solid plunger, A (fig. 4), is substituted for the piston, to avoid the expense of turning the cylinder true, and also because it resists better the wear from grease and dirt. At each stroke it raises a volume of water equal to that of the plunger.

Double-acting Force Pump.

This pump (fig. 5) sends up water both at the up and down stroke. At the up stroke the water above the piston is forced through the valve A, while that below enters the piston at the valve D; at the down stroke the water is forced through the valve C, whilst it enters above the piston at the valve B.

Fig. 4.

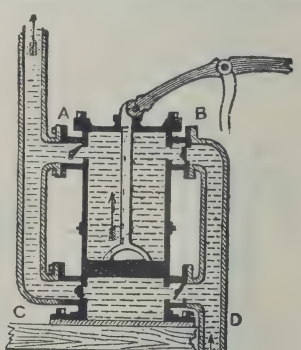

Fig. 5.

In all force pumps the packing of the piston or box is of great importance; it is commonly made of waste tow soaked in tallow and rammed tight; or for great pressures, cup leather packings are used.

Working Barrels, Buckets, and Valves.

These should be made of brass, gun-metal, or phosphor bronze, which metals, although costly in the first instance, will be found more durable, to require less repair, and to be more accurate in their operation than iron, being much less liable to injure the leather attached to the bucket and valve, the parts most frequently in want of repair.

An alloy which will withstand the action of water under pressure in a metal valve, and which is used by one of the largest firms in the country, consists of the following ingredients:—Copper, 10; tin, 1; zinc, $\frac{7}{16}$; lead, $\frac{1}{8}$.

The suction-pipe should be two-thirds the diameter of working barrel.

Pump Balancing.

To ensure equal work on the up and down strokes of a pump, it must be balanced. A complete balance provides for the whole weight of metal hung on the crank pin or beam, and one half the water work. The case of a bucket and plunger pump is perhaps the least simple, as in a bore-hole pump with a plunger at the surface delivering to a height above the surface.

Let A = area of bucket; a = area of plunger; W = weight of moving parts hung on crank pin and immersed in air; w = ditto immersed in water, e.g. the bucket and rods; H = height from water-level when pumping to plunger, in feet; h = height from plunger to point of delivery, in feet; B = balance weight to act at same lever arm as crank pin; then

$$B = W + 0{\cdot}875\, w + 0{\cdot}216 \left\{ [A \times H] + [(A - a) \times h] - [a \times h] \right\}.$$

The coefficient 0·216 represents one half the work, and the relation of pressure to head, or $0{\cdot}5 \times 0{\cdot}43$.

The correction for the different specific gravity of a gun-metal bucket may be neglected. Modern rods ultimately become as heavy as water, but at first have some negative weight. If a balance weight moves through a greater range than the cross-head, it must be correspondingly reduced.

Pumping from Wells.

For wells under 30 feet a 4-inch working barrel with a 9-inch or 10-inch stroke should be used. This size pump will throw 24 gallons per minute from a 20-feet well, and is as large as one man can conveniently work, and the best adapted for general use. For wells above 30 feet and under 70 feet a 3½-inch working barrel with a 9-inch or 10-inch stroke. For wells above 70 feet deep three 3-inch barrels, worked with a three-throw crank wheel and pinion in cast-iron case with fly-wheel, etc.

Artesian Well Pumps.

When the water level in a bore-hole is far below the surface, say 25 to 300 or 400 ft., it is necessary to place the pump barrel down the bore-hole, and it is usually desirable that it shall be lower than the rest level of the water, so as to be charged for starting work.

A bore-hole pump consists of a barrel of gun-metal with a bore at least 1 in. to 1¼ in. less than the diameter of the well lining tube. The barrel is screwed upon a rising main, which must be at least ⅛ in. to ¼ in. bigger than the barrel. The pump bucket and lower valve can thus be drawn up through the rising main for repair or inspection. A 4-in. pump will have a stroke of 1 to 3 ft. as desired, and a speed of 15 to 30 up strokes per minute. For durability it is desirable with very deep pumps to run at slow speeds. The pump rod terminates in a gun-metal rod or plunger, which passes through a stuffing box in the casting which forms the head of the pump. This head is flanged to the lining tube and screwed upon the rising main, and a branch is cast on one side for the water. If the lift above surface is considerable, it is possible partially or wholly to balance the lift of water to the surface by the use of a plunger, which may, if required, be as large in diameter as the bucket. However arranged, in order to equalise the work on the up and down strokes, it is proper to balance half the water lifting, and all the weight hung on the crank pin, so that the duty of the motive power may be evenly distributed in up and down strokes. Comparatively short pumps can be balanced by a weight in the main spur wheel on the crank shaft. When deeper, this is not sufficient, and a weighted lever may be linked to the crosshead pin and fitted with a balance weight on its outer or long end.

Some makers hang a heavy weight upon a pin in the face of the spur wheel, other makers attach wire ropes to the pump crosshead and pass them over a wheel and hang a weight, in guides, upon the ropes. Some engineers prefer to employ wooden pump rods, on account of their large displacement, so as to reduce the balance weights necessary.

A deep-well pump, unless small and slowly driven by a windmill, should be two to three diameters in length, of plain cylindrical form, with alternate grooves, with square-cut corners, and plain body. The grooves should be ¼ in. × $\frac{1}{16}$ in. and the space between, $\frac{5}{16}$ in., the two extreme spaces about ⅝ in. to ¾ in. No rings or packing leathers should be used.

The bucket valve may be mushroom, ball, or flat dermatine, the foot valve the same, in a taper casing, or foot piece which fits in the taper foot piece of the barrel. Under the bucket is a female screw which fits upon the thread projecting above the guard of the lower valve. When it is desired to remove the foot valve for inspection, it is lifted out by the bucket and pump rods, the bucket being lowered upon the valve and screwed to it; the valve then comes up with the bucket.

These pumps are usually driven from a second motion shaft by wheel and pinion, the second motion shaft carrying a fast and loose pulley driven by a belt from the engine or main shaft.

In country house work an oil-engine or an electric motor may be the driving agent, speed being reduced by more pairs of wheels or by larger driven wheels and pulleys. Or an electric motor may be worm-geared to the crank-shaft direct, in which case it is sometimes desirable to interpolate a friction clutch, so that the motor can be started off the load. Larger plants, such as the pumps for small town supplies, are perhaps best driven by gas-engines and suction gas plants.

Steel worms working in phosphor bronze wheels are said to give the best results. The wheel should be hollow faced so as partially to embrace the worm, and the angle of the teeth across the face of the wheel should be about 45°, so that the worm may require to be double or treble threaded to secure this. A thrust collar, or rather several collars, of propeller thrust type, are required on the worm shaft; but it is probably better to employ two worms, right and left, and two wheels connected to the same work, so that the thrusts balance, and no thrust block is required. The wheel should run in oil, which should be not too viscous. If a thrust block is employed, it should not be enclosed too narrowly, especially if near to the worm, as this has been found to prevent free access of oil.

When the water level in a bore-hole is not too deep below the surface, the air lift pump may be used with advantage, but it falls off in efficiency at great depths, and may often necessitate the boring of the well to depths very much greater than would be necessary merely to give the water yield. (*See also* Air Lift Pump, p. 1276.)

CAPACITY OF PUMP.

If
d = diameter of barrel, in inches ; s = stroke, in inches ; n = number of acting strokes per minute ; g = gallons per hour ; then

$$g = d^2sn \div 6, \text{ approximately.}$$

Semi-Rotary Pumps.

THE ORIGINAL 'ALLWEILER' SEMI-ROTARY WING PUMP.

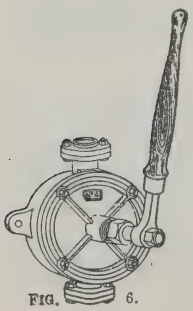

FIG. 6.

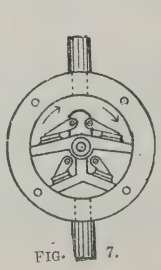

FIG. 7.

These pumps, figs. 6 and 7 (*W. H. Willcox & Co. Ltd.*), are made either double (as shown in the figs.) or quadruple acting. The working parts are of metal, and the wear and tear is reduced to a minimum ; they are claimed to be lighter and occupy less space than any other pumps of equal capacity, and are self-contained. Although fig. 6 shows a form for hand-working, these pumps are adapted for being fitted to any kind of motive power and can be employed for all general purposes.

PARTICULARS OF WILLCOX SEMI-ROTARY PUMPS.

12	—	—	—	8,300	On application.		

The capacities in the foregoing table are based on 3 ft. suction, 3 ft. delivery, and on a full stroke; but the pumps will lift 25 ft. and force to a height of about 70 ft., according to size and speed.

'Allweiler' Semi-Rotary Wing Pumps can be supplied with rubber balls for thick liquids, etc., and with phosphor bronze balls for acids, etc.

THE BOULTON WATER ELEVATOR.

This water elevator consists of an endless band to which are fixed a series of open-ended cells, so designed as to retain water by surface tension. The band is shown in fig. 8 and the general arrangement of the apparatus in fig. 9.

FIG. 8.

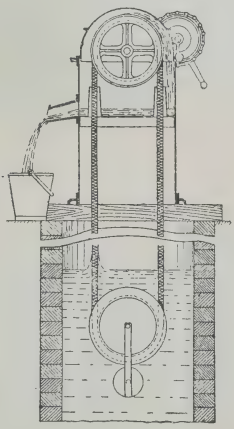

FIG. 9.

The band passes over a driving pulley at the top, carried in a suitable casing. At the lower end a weighted pulley is carried in the loop formed by the band and is submerged in the water.

When the top pulley is rotated the band is set in motion, carrying on the upward side water which is released in passing over the top pulley by centrifugal force breaking down the surface tension.

The bands are made in various sizes, both single and multi-element, ranging in output for power operation from 284 to 19,500 gals. per hour. For hand use outputs of 2·8 gals. per minute from 220 ft. deep, or 13 gals. per minute from 50 feet, can be obtained by one man.

The Boulton water elevator is suitable for dug wells of practically any depth; installations as deep as 410 ft. having already been successfully undertaken.

The efficiency is very high. From official independent test figures a band efficiency of over 95 per cent. on a well 150 ft. deep was recorded.

The headgears are made in various types to suit most purposes, both with and without force pumps, for delivering to heads above the elevator.

The elevator can also be used for handling sewage, sludge, etc., and the band and elements are practically non-corrodible.

On wells over about 30 ft. the cost is very much lower than ordinary deep-well pumps, and amongst its chief advantages are (1) ease of installation, there being no need to descend, and nothing to fix in the well; (2) simplicity—no valves, buckets, plungers, or pipes in the well; (3) it is unaffected by frost; (4) high efficiency; (5) suitable for wells where there is a big variation in water level; (6) the band is not an articulated construction, and has no pins or knuckles to wear or corrode.

STEAM PUMPS.

The Clarke Chapman Direct-Acting Feed Pumps.

(Woodeson's Patent.)

The single-cylinder direct-acting type of pump, on account of the small number of working parts and consequent small liability to break down, is very largely employed. Figs. 10 and 11, p. 1255, show Woodeson's 'Simple' Patent Direct-acting Pump (*Clarke, Chapman & Co. Ltd., Gateshead-on-Tyne*). This pump, which is extensively used, works with all steam pressures up to 400 lbs. per sq. in.

The steam chest is manufactured of the best hard close-grained cast-iron, of a suitable thickness to withstand any tendency to distort through the temperature of high-pressure steam.

The working parts of the steam chest consist of one auxiliary valve and one main valve, both of piston valve type.

The auxiliary valve is operated by the valve gear, actuated by the piston-rod crosshead. The main valve is partly moved mechanically and partly operated by steam, controlled by the auxiliary valve.

The action of the valves is as follows :—

When the main piston is nearing the end of its stroke, and the auxiliary valve commences to be moved by the valve gear, the first part of the movement closes the port through which the exhaust from one end of the main valve has been passing. The next part of the movement of the auxiliary valve opens steam to this end of the valve, and as the steam to the opposite end has not been closed, the main valve is in equilibrium. By the time that this takes place the auxiliary valve has moved so as to be in contact with the main valve, and further movement of the valve gear causes the auxiliary valve to move the main valve mechanically and so close the ports to the main cylinder. When these ports are nearly closed the auxiliary valve has closed the steam port at the end of the main valve, towards which the valves are moving, and opened an exhaust port, with the result that the main valve is moved by steam to the end of its travel and the steam cylinder ports are opened for the return stroke.

Should the main valve by any chance be delayed in being moved by steam, it would be worked mechanically during the clearance in the steam cylinder to a sufficient extent to open the steam port at the end of the cylinder towards which the piston was moving, and so forming a steam cushion to prevent the possibility of the piston striking the cover.

Advantages of the gear are :—

The main and auxiliary valves can all be mechanically actuated from the outside; this is an advantage if the pump is standing for any length of time, as it keeps the faces from getting rusted up.

During the process of the mechanical movement, the piston to which this movement is imparted is in perfect equilibrium.

Entire absence of valve setting.

These pumps are also made on the Tandem Compound principle. Great economy has been obtained with the pumps, and they are specially applicable for electric power stations and other high-class installations where economy of steam is an important consideration.

Fig. 12, p. 1255, shows a pair of these pumps fitted with automatic controlling gear, as used for Main Independent Feed-Pumps for Marine Purposes; with this automatic controlling gear there must be no dead points, and the pump must be able to start from any position, this being a special recommendation for a feed-pump for marine purposes, where, in order to derive all the benefits to be gained by using independent main feed-pumps, the speed of the feed-pumps must be automatically regulated according to the quantity of water to be dealt with, which varies with the speed of the main engines. The 'Woodeson' pump contains all the necessary features for this work.

No flat surfaces exist in any part of the water end exposed to pressure. Both suction and delivery valves are arranged in groups, and are easily accessible for overhauling. The plunger

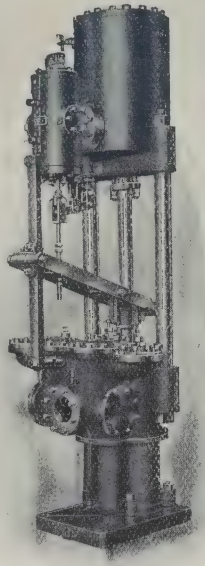

FIG. 10.

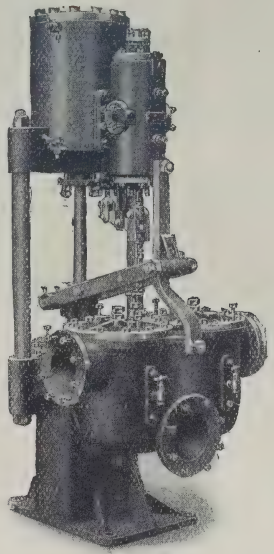

FIG. 11.

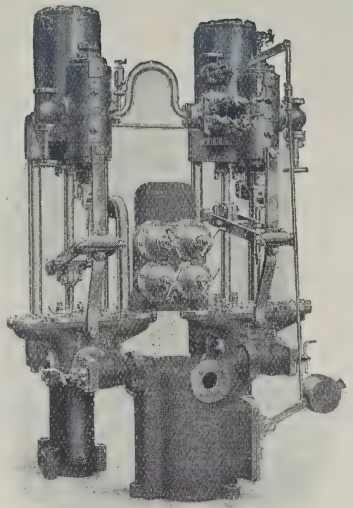

FIG. 12.

junks are of gunmetal, and are fitted with composition plunger rings, specially manufactured to deal with high pressure and high temperature.

Test taken with Clarke, Chapman Simple Type of Slow Speed Feed-Pump (Woodeson's Patent):—Diameter of steam cylinder, 10½ ins.; Diameter of water cylinder, 8 ins.; Length of stroke, 18 ins.; Water delivered per lb. of steam used, 81 lbs.; Steam used per water h.p. hour, 59·5 lbs.; Steam pressure per sq. in., 180 lbs.; Pressure in discharge pipes per sq. in., 195 lbs.; Efficiency of pump, 97 per cent.

Test taken with Clarke, Chapman Tandem Compound Type of Slow Speed Feed-Pump (Woodeson's Patent):—Diameter of h.p. cylinder, 8¼ ins.; Diameter of l.p. cylinder, 13 ins.; Diameter of water cylinder, 8¼ ins.; Length of stroke, 18 ins.; Water delivered per lb. of steam used, 110·5 lbs.; Steam used per water h.p. per hour, 36·5 lbs.; Steam pressure per sq. in., 195 lbs.; Pressure per square in. in discharge pipes, 215 lbs.; Efficiency of pump, 97 per cent.

The Warner Anthony Pump.

(*Robert Warner Pumps, Ltd., Newcastle-on-Tyne.*)

This pump is a distinct departure from the usual steam-operated gear fitted to most direct-acting steam pumps. The main difference lies in the fact that the whole of the working parts are self-contained and form a separate unit, which can be removed from, and replaced in, its valve chest by simply removing the steam chest cover, and without disturbing any adjustment. It is easily possible to shut down one of these pumps, take out the steam distribution unit, slip another unit in its place, and start up again, in five minutes. Pumps so fitted have run under adverse conditions night and day for upwards of two years without a stop.

Fig. 13, p. 1257, represents a section through a steam cylinder and valve chest with the unit in its working position in the chest. The main cylinder has an ordinary three-ported valve face on which works an ordinary slide valve B. The unit proper which bridges over this slide valve, but which is quite separate from it, consists of a small cylinder provided with faces which contact with port faces on either side of the main port face of main cylinder. Inside the cylinder A is a piston C attached to a piston rod E which passes up through the unit cylinder cover and has on its outer or upper end a circular head F, which fits into a separately formed recess in a small cover G in the top of the valve chest, which recess is so arranged that whilst the head of the piston rod can be withdrawn horizontally, no vertical motion is possible.

It will thus be seen that the usual arrangement is reversed, in that the piston C is held in one fixed position, while the cylinder A is free to move on it.

Through the lower end of the valve chest works the valve rod H attached by lever gear to the main piston rod, a fulcrum being provided by a bracket bolted to a lug on the main cylinder casting. The rod H is, like the rod E, provided with an enlarged circular head J, which works inside the hooded recess K formed in the lower end of the unit cylinder A.

Supposing now that steam is admitted to the bottom side of the main piston, the top side being open to exhaust, the sequence of operations is then as follows:

The main piston travelling upwards pulls the rod H downwards; when the rod has travelled down a certain distance, the head J engages with the lower face of the recess K and thus pulls down the cylinder A, and with it the slide valve B. At the moment when the head J engages with the lower face of the recess K, two small ports, which are arranged one on either side of the slide valve B, but which are not shown in the figures, come into register with two other small ports in the cylinder A, also not shown. When the main piston has nearly completed its stroke, and when the lower main steam port has been closed by the valve B, the head J has pulled the cylinder A so far that the small port on one side has passed over the edge of the main port face, while at the same moment the small port in the other side is put into direct communication with the main exhaust port, the result being that live steam is admitted to the lower end of the unit cylinder A, shooting it over the remainder of its travel and carrying with it the slide valve B. This action opens the upper steam port MSP 1 of the main cylinder to the live steam in the valve chest, and puts the lower main port MSP to exhaust. The same sequence of operations is then repeated, the unit in this case being pushed up instead of being pulled down.

In the sectional view the main piston is shown on its downward travel. The valve rod H travelling upwards has just come into contact with the upper face of the recess K of the unit cylinder, and is about to carry it and the slide valve up with it, so shutting off the upper main steam port MSP 1, after which the unit will be shot over by steam pressure acting at the right moment on the upper side of the fixed piston, this shooting it over and reversing the main valve B.

This system is fitted by Messrs. Warner to pumps for all duties, and is supplied by them to the British and Allied Admiralties and the principal users of this type of machinery.

The Weir Direct-Acting Feed Pump.

The Weir Patent Direct-Acting Feed Pump (*G. & J. Weir, Ltd.*), shown in fig. 14, p. 1259, is the original of a type of pump which is being largely used. Introduced at first for marine boiler feeding, its adoption by the mercantile marine, the British Navy, and numerous foreign navies, caused it afterwards to be placed on the market in a form suitable for land installations, power plants, etc.

The valve gear is positive—*i.e.* the steam valve can never be in such a position that the pump will not start immediately when steam is turned on. The only possible way in which the main

THE 'WARNER ANTHONY' PUMP.

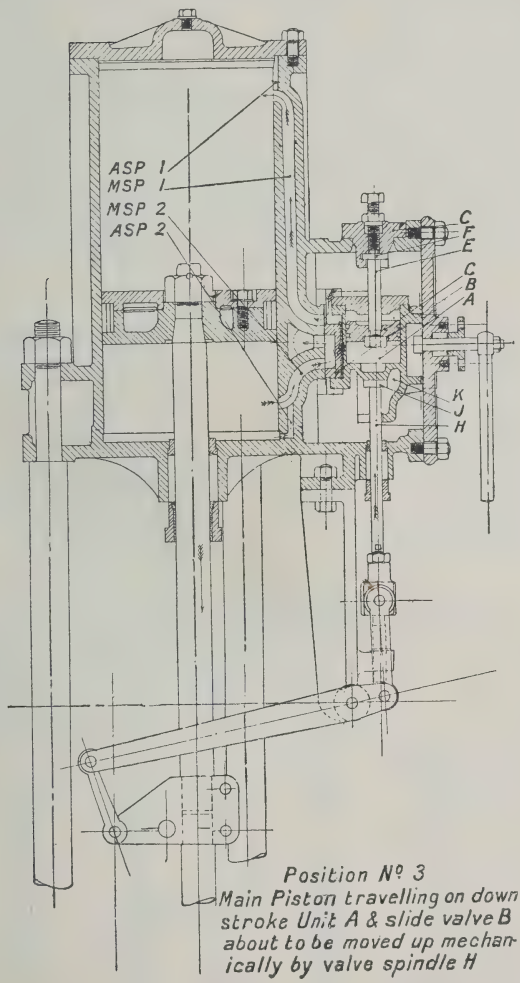

FIG. 13.

value can rest is at full travel, either for an up or down stroke of the piston. The valve arrangement also ensures constant length of stroke and certainty of action.

The steam valve is practically a D slide-valve, with a small auxiliary valve working on the back, and hence has not the same liability to leak as a piston valve. These are the only two moving parts proper in the steam chest, so that there is little opportunity for wear, and no delicate adjustments to get out of order. The steam is used expansively, and the cut-off can be regulated from the outside while the pump is working.

The water valves are of the Weir group type, providing a large area with only a small lift, thus ensuring easy working and little wear and tear. The pumps are designed to work at a moderate speed and the piston is slowed down towards the end of the stroke, enabling the valves to settle quietly in their seats. The working and maintenance of the pumps is therefore much more satisfactory than in pumps running at a high speed. In the matter of steam consumption, numerous tests and comparisons show that the Weir pump is highly economical; this is due to the fact that it has fewer ports and passages than a duplex pump, and the simple expansion arrangement enables it to be built so that the clearance is small.

The parts of each pump are of a standard size, made to gauge and interchangeable, and each complete pump is tested hydraulically and under steam before leaving the works.

Where it is desired to regulate the boiler feed automatically, a special design of float tank and regulating gear is furnished.

The Weir pumps are also supplied of the tandem compound and twin compound types.

Messrs. G. & J. Weir, Ltd., Cathcart, Glasgow, the makers, also list a line of these pumps for light service, tank duty, etc.

List of Parts.—(See fig. 14, page 1259.)

1. Steam slide valve chest.
2. Double joint.
3. Front stay.
4. Bottom spindle.
5. Valve gear levers.

THE WEIR DIRECT-ACTING FEED PUMP.

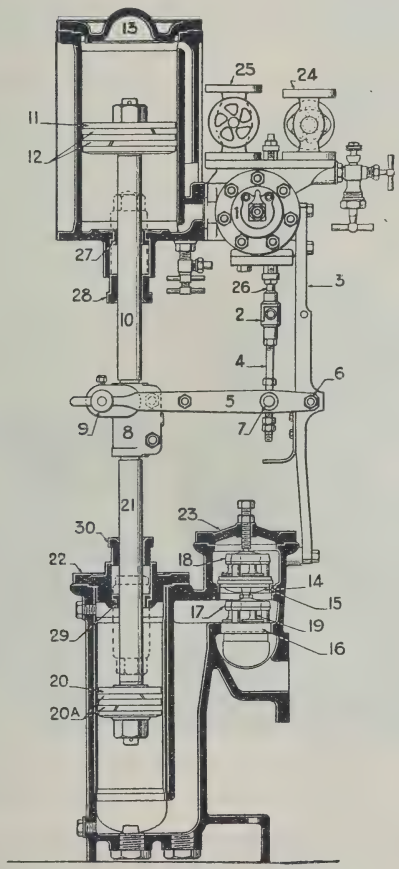

FIG. 14.

The Weir 'Turbo Feed' Pump.

(G. & J. Weir, Ltd., Cathcart, Glasgow.)

This pump, fig. 15, consists of a single pressure, multivelocity stage, impulse steam turbine, working in conjunction with a single stage centrifugal pump of special design.

The turbine casing and bearings are divided horizontally, the lower portions being embodied in the general framework or base of the set. This framework is extended at one end to form a flange, to which the pump casing is rigidly secured. By this arrangement the impeller of the pump is carried on the overhanging end of the turbine shaft.

By means of a suitable hydraulic governor, operating a balanced double beat throttle valve, the set is self-regulating for all ordinary changes in both water and steam conditions. When the latter are decidedly adverse, auxiliary nozzles may be brought into play by means of auxi-

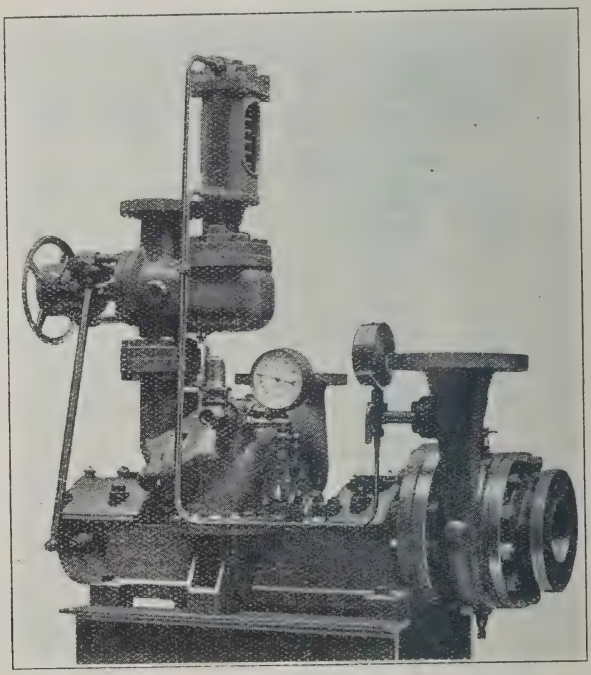

Fig. 15.—The Weir 'Turbo Feed' Pump.

liary valves in the nozzle box and the quantity of steam supplied to the turbine considerably augmented.

An emergency governor of the eccentrically-loaded ring type is provided, which, in the event of the speed of rotation exceeding a predetermined limit, actuates a trip gear which releases a spring and instantaneously closes the stop valve, and steam is completely shut off from the turbine. Thus there is no possibility of the speed of the set reaching unsafe limits in the event of an accidental failure of the supply ; and as the discharge pressure depends upon the pump speed only, the set cannot be seriously overstrained by sudden obstruction or closing of the discharge.

The turbine glands are provided with carbon packing, the bearings are of the self-oiling ring type, and the pump impeller is hydraulically balanced.

The Weir Turbo Feed Pumps are of sound mechanical construction and all parts are readily accessible for examination and overhauling. They are entirely automatic in action and are noiseless and free from vibration.

Nine Elms Iron Works, READING.

F. 1261

The pumps are capable of discharging against the highest boiler pressures and are specially suitable for large units. They can be used to work in conjunction with ordinary reciprocating pumps, and are made in multi-stage types for high pressures.

A special feature of the Weir Turbo Feed Pump is its economy in steam consumption. Further, as the exhaust steam contains no oily residue, it is available for heating the feed water by direct contact, thereby utilising all the heat in the steam. In this connection Messrs. Weir have introduced a nozzle heater which has been specially designed for working in conjunction with these pumps.

The Weir Turbo-Feed Pump has been adopted by the British Admiralty and the leading Municipalities and Electric Power Corporations, including the Corporations of Cardiff, Glasgow, Greenock, Halifax, Norwich, Poplar, Salford, West Ham, Wolverhampton, Woolwich, the Clyde Valley Electric Power Co., and Treforest Electrical Consumers, Ltd.

The Pulsometer Steam Pump.

In this pump (*The Pulsometer Engineering Co., Ltd.*), figs. 16 and 17 (general view), the neck J contains a gun-metal ball I, above which is a steam pipe K. EE are suction valves placed at the base of two chambers AA. Immediately above the suction valves the two chambers com-

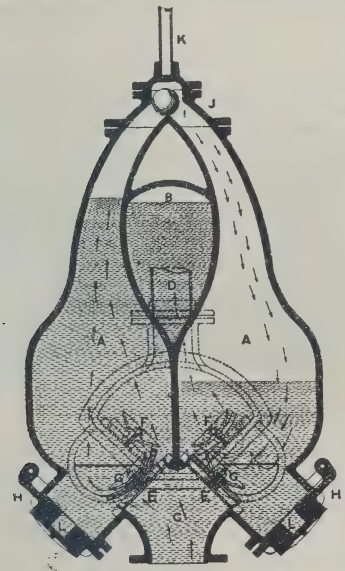

Fig. 16.

Fig. 17.

The Pulsometer Steam Pump.

municate with a ' discharge box ' through two discharge valves FF. The valves in the standard pattern of pump are of the grid type, consisting of a grid, rubber, and guard. In addition to the above valves there are three small gun-metal valves (not shown in the figure) for the admission of air, one of each being screwed into the upper part of the two water chambers and the air vessel.

Action.

Assuming one of the chambers to be open to steam and full of water, the steam entering by the steam pipe and past the ball passes into the chamber and presses upon the small surface of water exposed, depresses it without agitation (and therefore with little condensation), and drives it (as seen in the figure) through the discharge valves FF into the rising main, D. The moment the water in the chamber falls to the level of the opening in the branch leading to the discharge box, the steam blows through with a certain amount of violence, and as it is brought into intimate contact with the water in the discharge box an instantaneous condensation takes

place, and the vacuum thus formed in the emptied chamber immediately pulls the control ball over on to the corresponding seat and cuts off further admission of steam, allowing the vacuum to be completed. Water immediately enters through the suction pipe, and lifting the inlet valve rapidly fills the chamber again. A similar operation has been taking place in the fellow chamber, the period occupied by filling one chamber corresponding to that of emptying the other, and these operations continue alternately in the two chambers so long as the pump is supplied with steam and water. The function of the air valves is to introduce a small quantity of air at each stroke or 'pulsation' for the purpose of cushioning the ball when it changes its position, and for separating the steam from the water by a non-conducting film so as to prevent loss by condensation during the expulsive portion of the cycle.

The 'Pulsometer' Steam Pump will work just as well suspended from a chain or rope as when permanently fixed. Its very small size, in proportion to the quantity of water thrown, makes it available in a great many situations where no other pump can be applied. Another important feature is its ability to pump water heavily charged with mud and sand. For these reasons it is very largely used by contractors for pumping from excavations.

The 'Pulsometer' Steam Pump will, where the conditions remain constant, work day and night without attendance—in fact, as long as steam and water are supplied to it.

Boiler Pressure Required for Pumping.

What boiler pressure would be required to operate a direct-acting steam pump having an 8-in. diameter steam cylinder and a 6-in diameter water cylinder, for pumping water to a height of 100 ft. with the suction water supplied at a pressure of 10 lbs. per sq. in.?

The mechanical efficiency of a pump of the stated size, when in good working order, would be about 65 per cent. The pressure pumped against would be $100 \times 0{\cdot}433 = 43{\cdot}3$ lbs. per sq. in. due to the head, plus the pressure required to overcome friction of the water in the discharge pipe, the latter depending on the rate of pumping, and the diameter, length, and fittings of the discharge pipe. Under ordinary conditions the loss of pressure from pipe friction would be no greater than 10 lbs. per sq. in., and if assumed to be equal to the suction pressure the net resistance to movement of the water piston would be $(6 \times 6 \times 0{\cdot}7854) \times 43{\cdot}3 = 1{,}224$ lbs. With 65 per cent. mechanical efficiency of the pump, the resistance to be overcome by the steam piston would be $1{,}224 \div 0{\cdot}65 = 1{,}883$ lbs., and for overcoming that resistance the effective pressure required to be exerted on a direct-acting 8-in. diameter steam piston would be $1{,}883 \div (8 \times 8 \times 0{\cdot}7854) = 37{\cdot}46$ lbs. per sq. in. The required boiler pressure will need to be equal to the effective pressure plus the back pressure and the reduction of the boiler pressure by throttling in the steam pipe and steam passages of the pump. Allowing a back pressure of 4 lbs. and reduction by throttling of 10 lbs. per sq. in. would require a boiler pressure of $37{\cdot}46 + 4 + 10 = 51{\cdot}46$ or about 52 lbs. per sq. in.

Willcox's 'Penberthy' (Regd.) Cellar Drainer.

This is a Water Pressure Ejector (*W. H. Willcox & Co. Ltd.*) of high capacity, for use in removing water from cellars, inspection pits, stokeholes, lift pits, or wherever it is desired to keep water or other liquids from rising above a certain level. It is automatically operated by a float-controlled, quick opening and closing valve. This valve is never partially opened; it cannot leak, and allows the ejector to give its greatest efficiency by working to full capacity. The float arm is slotted where it connects to the valve lever; this prevents the ejector from operating until the water has raised the float up to the highest point, and, as the water is ejected, the arm travels down the length of these slots before the weight of the float affects the valve.

To facilitate the installation of this drainer in small holes or sumps it is made as compact as possible. The float, instead of being round, is flat on the top; this gives it more buoyancy and occupies less space than would a round float of the same diameter. To further economise space the float is built around the suction pipe. This arrangement (patented) has the advantage of being rigid, and overcomes all the trouble of a loose float. The balance of the drainer is built directly above the float; this not only keeps the whole machine in as small a space as possible, but also keeps all working parts, with the exception of strainer and float, above the water, thus preventing corrosion or the exterior parts becoming clogged up by deposits of slime, dirt, or sediment. The interior parts are prevented from coming into contact with any foreign particles by a special strainer, which is so constructed that instead of the water being drawn directly upward, it is taken in at the sides, allowing all sediment to collect under the strainer without being disturbed by the force of the suction. A foot valve is provided inside the strainer, which closes the instant the drainer ceases operating, holding all water in the pipes, all primed for starting instantly at the next filling of the sump.

The following tables show the capacities at different pressures and elevations, dimensions, pipe sizes, weights, etc.:

TABLE OF CAPACITIES OF WILLCOX-PENBERTHY CELLAR DRAINERS AT DIFFERENT PRESSURES AND ELEVATIONS, PIPE SIZES, ETC., MODEL 'R.'

Size and Model.	Pipe Sizes. Ins.		Working Head in ft.	Maximum Net Capacities from Sump, in Gallons per Hour at 10 to 100 lbs. Water Pressure.								
	Supply	Discharge		10	15	20	25	30	40	60	80	100
No. 1 Model R	¾	1	3	80	*210*	*300*	*340*	*400*	*510*	*700*	*720*	*700*
			6		90	140	*240*	*300*	*390*	*570*	*670*	*690*
			9			90	150	210	*330*	*480*	*620*	*660*
			12				100	150	220	*390*	*550*	*630*
			15					90	190	*300*	*450*	*600*
			18						120	250	*320*	*550*
No. 2 Model R	¾	1½	3	190	*390*	*550*	*620*	*750*	*910*	*1180*	*1240*	*1220*
			6		210	340	*420*	*600*	*750*	*1020*	*1140*	*1200*
			9			210	300	380	*540*	*900*	*1090*	*1150*
			12				210	300	420	*780*	*1020*	*1110*
			15					210	370	*570*	*940*	*1050*
			18						300	510	*850*	*970*

The model 'R' drainer requires 5 lbs. water pressure or more for each one foot of elevation, while a low-pressure drainer can be supplied which will work on 2 lbs. to 4 lbs. per foot of elevation.

TABLE OF CAPACITIES OF WILLCOX-PENBERTHY CELLAR DRAINERS AT DIFFERENT PRESSURES AND ELEVATIONS, DIMENSIONS AND PIPE SIZES, MODEL 'L.'

Size and Model.	Pipe Sizes. Ins.		Working Head in ft.	Actual Capacities in Gallons of Water per Hour taken from Sump, and Not Total Amount of Discharged Water.			
	Supply.	Discharge and Suction.		At 25 lbs. will elevate	At 40 lbs. will elevate	At 60 lbs. will elevate	At 80 lbs. will elevate
No. 3 Model 'L'	1	1½	3	660	1100	1440	1650
			6	520	860	1230	1440
			9		720	1050	1320
			12			840	1040
			18				760
No. 4 Model 'L'	1½	2	2	960	1600	2020	2400
			6	760	1240	1880	1980
			9		1040	1600	1800
			12			1280	1440
			18				1050
No. 5 Model 'L'	1½	2½	3	1280	2100	2700	3200
			6	1000	1620	2300	2820
			9		1260	1960	2600
			12			1560	2060
			18				1500

The above capacities are the actual capacities of water taken from sump, and not the combined discharge of operating and drainage water as given in most tables. For higher elevations than shown above, special drainers can be made.

'PENBERTHY' (REGD.) AUTOMATIC CELLAR AND SUMP DRAINER.

(New Electric Model.)

This model is the latest addition to the 'Penberthy' (regd.) Cellar Drainer, and is operated by electric current instead of by water pressure. It operates only when water accumulates, causing the float to rise and make contact by means of a special mercury type switch, and immediately ceases action when the water has been disposed of and float falls.

It is designed for fitting in a sump, which should be not less than 15 to 18 in. diameter by 2 ft. deep, and may be constructed of a piece of earthenware sewer pipe, cemented at the bottom, or of brick or concrete. A cover (constructed of almost any material) is desirable, to keep out dirt and refuse.

The pump outlet should be connected to the nearest sewer, drain, or surface outlet, and the electric lead should be plugged into the nearest plug or light socket, when the Drainer is ready for operation.

The arrangement is particularly suitable in cases (*a*) where town water pressure is not available or is very low; (*b*) where excessive quantities of seepage water have to be handled; (*c*) where discharge heads are up to 20 ft.; (*d*) where low cost of operation is an important factor.

Size No.	Pipe Connection.	Approximate Discharge Capacities per hour.				Size Motor.
		5-ft. Lift.	10-ft. Lift.	15-ft. Lift.	20-ft. Lift.	
		Galls.	Galls.	Galls.	Galls.	H.p.
1 E	1 in.	900	700	500	—	¼
2 E	1¼ ,,	2500	2000	1500	600	½

Motor must be above sump hole floor level so as to secure proper ventilation and avoid dampness.

Pump Valve Materials.

Dexine.

Dexine (*Dexine, Ltd.*) is a preparation of vulcanised indiarubber and other ingredients manipulated by a special process; it is an exceedingly tough and frictionless material which has been proved to withstand the action of oils and chemicals. It is extensively used for valves, in the place of ordinary indiarubber, and can be obtained in any degree of hardness, suitable for straight or curved guards and pumps of all descriptions and of all dimensions.

Valves made of Dexine are claimed to retain all the resiliency and natural cohesion of pure Para rubber—which enters into its composition to a certain extent—and is, in addition, rendered immune from the detrimental influence of acids, oils, alkalies, or grease. The material can be moulded to any shape, and vulcanised to any degree of hardness or flexibility to suit any particular purpose.

Dexine is also used to form the 'bucket or cup leathers' of pumps, up to 20 ins. diameter. In round or square section, or in the form of U rings, the material makes an efficient packing for compressor rods, and, having a low coefficient of friction, the wear on the material is very slight.

Hydraulic Packings.

Ram or 'U' Leathers.

A cupped leather packing (ram or 'U' leather) forms a self-tightening packing, and is very generally used, although if it is not properly made, and if the cup is not strengthened at the bend (where the greatest friction is), the leather soon wears out and fails.

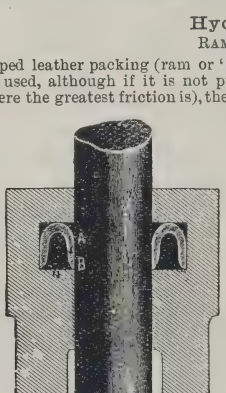

FIG. 18.

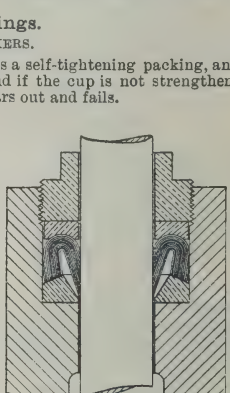

FIG. 19.

Fig. 18 shows a ram leather in its position. The water gets behind the leather and presses it tightly against the ram; the friction occurs mainly at part A, and increases as the pressure of water increases. There is not much friction at the portion between A and B, and the efficiency of the press is but little altered by making AB greater or less. It is, however, asserted by some that the distance AB is of importance, but this is on account of deterioration. The part AB is constantly in states of tension and compression, and if the leather is

not good and well made it is liable to crack. Leathers are very frequently made too deep, and this leads to their being more liable to crack and fail; a shallow leather is undoubtedly the best—it works just as well as a deep one, and in making the leather considerably less strain or pull is required to block or mould it than would be the case with a deep one.

Too much stress cannot be laid on the necessity for using leather packings of the best quality and make only. It is equally important to consider the question of tannage. The value of a tannage depends upon its suitability and adaptability for different classes of work. Low pressure work, for example, requires a different tannage and fibre from high pressure, and medium pressure a tannage and fibre between the two.

Fig. 19 shows a Patent 'SEA' Ring of compressed cotton layers supplied for packing purposes.

Pump Leathers and Packings.

'SEA' rings are specially designed with a view to a higher efficiency than may be obtained by the use of the ordinary leathers. Fig. 20 shows a double-acting plunger fitted with two 'SEA' ring cups separated by metallic junk-ring, and fig. 21 shows a 'SEA' ring collar fitted to a hydraulic or other ram. It is claimed that these ring packings will wear indefinitely where the ordinary leather would wear out and crack in a very short time. The rings are able to resist high temperatures, and are used with success for extremely high pressures. They are

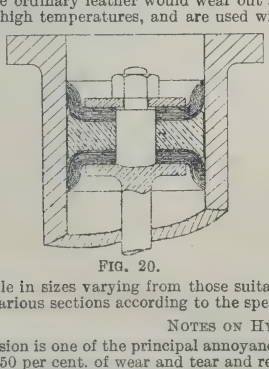

Fig. 20.

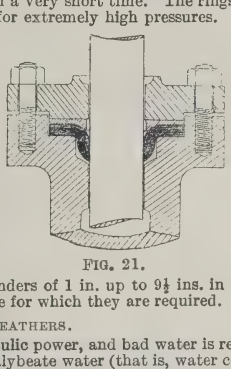

Fig. 21.

obtainable in sizes varying from those suitable for cylinders of 1 in. up to 9¼ ins. in diameter and of various sections according to the specific purpose for which they are required.

Notes on Hydraulic Leathers.

Corrosion is one of the principal annoyances of hydraulic power, and bad water is responsible for fully 50 per cent. of wear and tear and repairs. Chalybeate water (that is, water containing iron) is about the worst.

Where dirty or gritty water has to be used the leathers wear away very rapidly. When the leathers are not kept constantly under pressure, if the pressure is taken off, the water gets between the leather and the ram, and as soon as the pressure comes on again, a little gritty or dirty water passes between the leather and the ram and causes the wear of the packing; it also scaives or flutes the ram. A remedy for this consists in putting a relief valve on the pipe that delivers the water to the accumulator from the pump, and in leaving the suction valve always open. The pressure in this way is always kept on the leather, preventing leakage, and at the same time saving considerable wear and tear of the packing.

It is important and essential that a leather should be well rubbed and worked with tallow before putting in. A good plan is to fill the inner space of the leather with neatsfoot oil or sperm, about an hour before putting in. *Never use mineral oil for rams or cylinders*, it runs away quickly, through being thin, and also renders the leathers rotten and pulpy.

For lubrication, Entwistle's patent lubricant (Patent No. 16,292; 1894), which contains 50 parts stearine or tallow, or other similar substance, 20 parts soapstone or powdered mica or talc, 2 parts graphite, 10 parts neatsfoot or other oil, 10 parts powdered zinc, lead, copper, or other soft metals, and 10 parts oil of tar, has given excellent results; the particles of metal, by the motion of the ram up and down, fill up any indentations, pores, or rough surfaces there may be on the ram or in the cylinder, and being of a soft or yielding nature (not gritty) distribute themselves over the rough surfaces.

Friction of Accumulator Cup Leathers.
